Care should be taken if there is a concern for TM perforation. As noted, quinolone drops have a better safety profile than neomycin-containing drops, which are ototoxic, especially after prolonged or repeated use. Having the patient lie down for 5 minutes after the solution has been placed may obviate the need for packing. Commercially available wicks made of compressed cotton or hydroxycellulose facilitate medication delivery. The wick is placed 10 to 12 mm into the canal, moistened with antibiotic drops, and left in place for 2 to 3 days. The wick generally falls out or, if left in place, may become a foreign body in the ear. Therefore, a patient should follow up with her or his primary care physician. There is no evidence that systemic antibiotics alone or in combination with topical preparations improve treatment outcome compared with topical antibiotics alone, but systemic medication, such as ciprofloxacin (500 mg bid), are indicated for immunocompromised patients with diabetes or HIV infection or for those with infections involving the skin and periauricular areas. OE can be extremely painful, and severe symptoms may require opiate analgesia. Topical anesthesia, such as benzocaine with or without antipyrine, may also be used for pain relief.

### Disposition

Patients with otitis externa rarely require admission. If it does not respond to therapy in 2 to 3 days, other conditions such as necrotizing external otitis should be considered. Patients who have a wick placed should be evaluated in 2 to 3 days to ensure improvement of the condition and that the wick is removed.

### NECROTIZING (MALIGNANT) EXTERNAL OTITIS

#### Principles

Previously known as malignant otitis externa because of its associated high mortality rate, necrotizing external otitis (NEO) is an extremely form of OE. Patients affected include older diabetics, those with acquired immunodeficiency syndrome (AIDS) and, rarely, immunocompromised children. *Pseudomonas* is the predominant pathogen, but *S. aureus*, *S. epidermidis*, *Proteus mirabilis*, *Klebsiella*, *Aspergillus*, and *Salmonella* have all been described as causative organisms. The infection begins in the external canal and progresses through the periauricular tissue and cartilaginous bony junction of the external auditory meatus. It then spreads into the adjacent tissues along clefts in the floor of the meatus known as the fissures of Santorini. It may spread to the base of the skull at the temporal bone, with a resultant skull-base osteomyelitis, another term often used to describe this entity. The facial nerve is the first cranial nerve affected, but other nerves may also be involved. The pathogenesis is uncertain but may be related to vascular insufficiency or immune dysfunction.
Clinical Features

Patients may have persistent otorrhea unresponsive to topical medications, severe otalgia, headache, and periauricular pain and swelling. The diagnosis should be considered in patients at risk who have a prolonged course of OE. The characteristic clinical finding is granulation tissue on the floor of the ear canal at the bony cartilaginous junction. Cranial nerve VII is most commonly involved; involvement manifests with facial paralysis, which occurs when the stylomastoid foramen is involved. Further extension can result in involvement of the glossopharyngeal, vagal, spinal accessory, hypoglossal, trigeminal, and abducens nerves. Cranial nerve involvement is not associated with increased mortality rates. Additional complications include meningitis, brain abscess, and thrombosis of the sigmoid sinus.

Differential Diagnoses

Patients with necrotizing otitis will present with severe ear pain. Other differential considerations include severe otitis externa, otitis media, otitis media complications, trauma, and referred pain from the teeth, sinuses, throat or temporal mandibular joint.

Diagnostic Testing

There is no single diagnostic criterion for necrotizing external otitis. The diagnosis is made from a range of clinical, laboratory, and radiographic findings. The C-reactive protein (CRP) level and erythrocyte sedimentation rate (ESR) may be elevated, but they are nonspecific markers. In the ED, computed tomography (CT) is the initial study of choice and, in most cases, will identify bony erosion and soft tissue abnormalities. Magnetic resonance imaging (MRI) is better at delineating responses to therapy. This disease should be considered in all patients with risk factors who have failed to respond to antimicrobial therapy for temporal bone inflammation and otalgia.19

Management

If NOE is suspected, consultation should be made with an otolaryngologist. The patient presentation will determine disposition. Patients who appear ill require admission for IV fluoroquinolones, such as ciprofloxacin, 400 mg IV q8h, to ensure that there is an adequate clinical response. The patient can then be switched to oral ciprofloxacin, given its bioavailability and penetration to bone. Treatment may be required for 6 to 8 weeks. Although extensive surgical treatment was previously required, its use is now limited to diagnostic confirmation or debridement of granulation tissue. Although some have recommended hyperbaric treatment for advanced disease with significant skull base or intracranial involvement, there is little evidence of its effectiveness.

Disposition

The decision for admission versus outpatient management should be made in consultation with an otolaryngologist.

MASTOIDITIS

Principles

Mastoiditis is the most frequent suppurative complication of OM, although the incidence of acute and chronic mastoiditis has decreased significantly since the advent of antibiotics. Although it is still associated primarily with AOM, some patients have not had a preceding episode of OM. Mastoiditis also has been described as a complication of leukemia, mononucleosis, sarcoma of the temporal bone, and Kawasaki disease.

Acute mastoiditis is a natural extension of middle ear infections because the mastoid air cells are generally inflamed during an episode of AOM. The aditus ad antrum is a narrow connection between the middle ear and mastoid air cells. If this connection becomes blocked, a closed space is formed, with the potential for abscess development and bone destruction. The infection may spread from the mastoid air cells by venous channels, resulting in inflammation of the overlying peristomeum. Progression results in the destruction of the mastoid bone trabeculae and coalescence of the cells, resulting in acute mastoid osteitis or coalescent mastoiditis. The resulting pus may track through many routes: (1) through the aditus ad antrum, with resultant spontaneous resolution; (2) laterally to the surface of the mastoid process, resulting in a subperiosteal abscess; (3) anteriorly, forming an abscess below the pinna or behind the sternocleidomastoid muscle of the neck (often called a Bezold abscess); (4) medially to the petrous air cells of the temporal bone, resulting in a rare condition known as petrositis; and (5) posterior to the occipital bone, resulting in osteomyelitis of the calvaria or a Citelli abscesses.

Chronic mastoiditis is generally a complication of chronic OM. There may be extensive invasion of granulation tissue from the middle ear into the mastoid air cells. Another entity, latent or masked mastoiditis, also has been described. It is indolent in nature, with minimal signs and symptoms, little or no fever, and a history of otalgia. The TM may be intact or perforated. Suspi-

\textbf{Clinical Features}

Clinical findings in acute mastoiditis include fever, headache, otalgia, and erythema. Pain is universally present. There are no specific diagnostic criteria, but the most common physical findings are postauricular erythema and tenderness, protrusion of the auricle, and an abnormal TM. The TM is similar to that in AOM—erythema, bulging, and decreased mobility—but may be normal in 10% of cases. Suspicion should be heightened if symptoms of AOM have lasted longer than 2 weeks. In chronic mastoiditis, symptoms include persistent drainage through the perforated TM, redness, edema, and retroauricular sensitivity.

<tbody>
<tr>
<td>The differential diagnosis includes severe otitis media, external otitis, skull fracture, lymphadenopathy or lymphadenitis, and deep space neck infections.</td>
</tr>
</tbody>
</table>

Diagnostic Testing

Although the diagnosis of mastoiditis can be made clinically in patients with typical findings, a CT scan is indicated in patients with neurologic symptoms, when an intracranial complication is suspected, or there is failure to improve with conservative therapy.22 Fig. 62.1 is a CT scan of acute mastoiditis.
PART III

Management

The initial treatment of choice in the emergency department is the administration of antibiotics, such as vancomycin, 15 to 20 mg IV bid, and a third-generation cephalosporin such as ceftriaxone (50 mg/kg per day). Surgical procedures may range from myringotomy and tympanostomy tube placement (for drainage and identification of the offending organism) to mastoidectomy and drainage for more extensive disease progression.

Disposition

Hospitalization is usually necessary for the administration of IV antibiotics. Early otolaryngologic referral is also recommended for possible aspiration and drainage of the middle ear, as well as the management of any potential complications.

SUDDEN HEARING LOSS

Principles

Sudden sensorineural hearing loss (SSNHL), defined as the idiopathic loss of hearing of 30 dB over at least three test frequencies occurring over a period of less than 3 days, is considered an otolaryngologic emergency. Any age group can be affected, but the peak incidence occurs in the fifth or sixth decade of life, with an equal gender distribution. The overall incidence ranges from 5 to 20/100,000 people/year. Its severity ranges from difficulty with conversation to complete hearing loss.

SSNHL is idiopathic in 70% of cases, infectious in 13%, and related to otologic disease, trauma, vascular disease, hematologic disorders, or neoplasm in the vast majority of other cases. A delay in diagnosis is common because the patient may report ear fullness that is often attributed to cerumen impaction or congestion from upper respiratory infections. Tinnitus is a common finding. The likelihood of recovery is related to the severity of the hearing loss, age of the patient, and associated vestibular symptoms. A history should include the time of onset, history of trauma or recent illnesses, medications, and presence of otologic and neurologic symptoms.

Clinical Features

The physical examination includes a thorough inspection of the external canal and TM integrity.

Differential Diagnoses

The differential for hearing loss is broad and can be differentiated into causes that involve the outer, middle, or inner ear. Outer ear causes include cerumen impaction and OE. Middle ear causes include otitis media and tympanic membrane perforation. Inner ear causes include medications, barotrauma, and autoimmune disease.

Diagnostic Testing

Weber’s test for hearing and Rinne’s test may help in distinguishing conductive versus sensorineural deficits. A comprehensive neurologic examination, including cranial nerve and cerebellar testing, may localize brainstem involvement. Laboratory testing and CT scanning are not indicated in the ED evaluation unless the physical examination points to a space-occupying lesion (ie, focal neurologic deficits not referable to the ear). MRI of the brain with gadolinium is the study of choice to identify retrocochlear pathology but should be performed in consultation with an otolaryngologist.

Management

A tapered dose of oral steroids is the most common treatment, although their efficacy is unproven. The dose is 1 mg/kg, up to 60 mg, tapered over 10 to 14 days. Additional treatments have included intratympanic steroids, hyperbaric oxygen, antiviral therapy, zinc, and magnesium, all with mixed results. Given the lack of treatment options for this condition, we recommend that a steroid taper be offered.

Disposition

Patients should get expeditious ENT referral on discharge from the ED.

EPISTAXIS

Principles

Epistaxis is a common otolaryngologic problem, with 60% of people experiencing it in their lifetime, although only 6% require medical treatment. It accounts for about 1 in 200 emergency room visits, with less than 0.2% ultimately requiring hospitalization. There is a bimodal distribution of children younger than 10 years and adults older than 50 years. Epistaxis is more common in colder seasons and in northern climates because of decreased humidity and subsequent drying of the nasal mucosa. Nasal bleeding is a frightening condition for patients but is seldom life-threatening. A solid understanding of physiology and treatment allows for prompt and efficient management of the disorder.

Anterior epistaxis accounts for 90% of all nosebleeds and usually involves Kiesselbach’s plexus on the anteroinferior nasal septum. Epistaxis is unilateral and can be controlled with anterior packing. Accounting for 10% of nosebleeds, and usually arising from a posterior branch of the sphenopalatine artery, posterior epistaxis differs from anterior bleeding in that it is more severe and occurs mostly in older adults with multiple comorbidities.

Three arteries with anastomoses between them supply the nasal area. The sphenopalatine artery supplies the turbinates and...
meatus laterally and the posterior and inferior septum medially. The anterior and posterior ethmoidal arteries from the opthalmic branch of the internal carotid artery supply the superior mucosa medially and laterally. The superior labial branch of the facial artery provides circulation to the anterior mucosal septum and anterior lateral mucosa (Fig. 62.2).

There are many reasons for epistaxis, but the most common are an upper respiratory infection with concomitant mucosal congestion and vasodilation and trauma, either accidental or iatrogenic (ie, nose picking: Box 62.1).

Clinical Features

A past medical history with particular emphasis on trauma, medical conditions, and medications that could cause epistaxis should be elicited. Patients often are anxious and hypertensive. An elevated blood pressure is usually from stress and anxiety and resolves with treatment. Hypertension has never been shown to cause epistaxis, although it can worsen the bleeding when present. Sedation with a benzodiazepine or narcotic may help these patients.

Differential Diagnosis

The differential diagnosis includes nasal trauma, infections, nasal foreign bodies, and bleeding disorders.

Diagnostic Testing

Identifying the source of the bleeding is often difficult. If the nose is actively bleeding, the patient should clear clots by blowing the nose and then applying bilateral pressure on the nasal septum by compressing the cartilaginous part of the nose for 10 to 15 minutes. Spraying oxymetazoline into each nare twice before applying pressure will optimize hemostasis and facilitate inspection after the pressure is released. This simple maneuver also educates the patient on how to self-manage further episodes. It is important to optimize the examination. The floor of the nose should be parallel to the room floor. If the head is tilted, only the anterior and upper aspect of the nares can be visualized. The nasal speculum should be opened in a vertical direction rather than side to side in the nares, so as not to obscure the septum, which is the area of greatest interest. During this time, materials for illumination, suction, visualization, and treatment should be assembled. Discharge without identification and treatment of the bleeding site often results in recurrences. Anterior clots may give the appearance of posterior epistaxis if the blood runs posteriorly. Persistent bleeding should be controlled with pledgets soaked in cocaine, lidocaine-epinephrine, or oxymetazoline to promote vasoconstriction and anesthesia. Routine laboratory testing is usually unnecessary unless the patient is anticoagulated or has an underlying condition.

Management

Identify and treat the source of bleeding, because the most significant risk factor for recurrent bleeding is not identifying the bleeding point. Application of silver nitrate chemically cauterizes the area but is often unsuccessful during active bleeding, so hemostasis should be secured first. With 4 to 5 seconds of application, nitric acid is formed and coagulates tissue. Coagulation should never be maintained longer than 15 seconds because septal damage may occur. The area should be cauterized from the periphery to the center and superiorly to inferiorly to avoid blood, which renders the silver nitrate sticks ineffectual. Bilateral application of silver nitrate to the septum is not advised because it may deprive the septum of a blood supply and theoretically could lead to necrosis.
If cautery is unsuccessful, topical thrombogenic agents, such as absorbable gelatin sponge (Gelfoam) and absorbable knitted fabric (Surgicel), can be tried. Tranexamic acid may be an option if bleeding continues. Tranexamic acid works by irreversibly binding and blocking the lysine binding sites on plasminogen molecules, resulting in inhibition of plasminogen activator and fibrinolysis. It has also been successfully used in 109 patients and resulted in much quicker resolution of bleeding and faster ED discharge when compared to nasal packing. The injectable solution (500 mg in 5 mL) is applied to a 15-cm nasal pledge and applied to the anterior nares.

If bleeding persists, the next step is the use of a nasal tampon. Nasal tampons work by three mechanisms: direct pressure, decreased bleeding from mucosal irritation from the foreign body, and indirect pressure from further surrounding clot formation. Cutting them to fit the contour of the nares and lubricating them with an antibiotic ointment makes the application easier. For large noses, a second tampon may be required. Occasionally, for uncontrollable bleeding despite the presence of a tampon, a second tampon should be inserted into the opposite nare. If bleeding still continues, a nasal balloon catheter with fibrin colloid material, such as Rapid Rhino (Smith & Nephew, Austin, TX), may be used. These devices are moistened with saline, so lubricants are unnecessary. They are placed in the floor of the nose and inflated with air. The fibrin colloid forms a hemostatic dressing. A second balloon in the opposite nose may be required if one side is unsuccessful.

Toxic shock syndrome (TSS) due to S. aureus has been reported in patients with nasal packing. Although many providers prophylactically give antibiotics after nasal packing, no study has shown that antibiotics are preventive for TSS or sinusitis, and the incidence of TSS is rare (16/100,000 population). We do not recommend routine antibiotic prophylaxis after nasal packing. Packing is uncomfortable and the patient may require opioids in the ED and on discharge. The packs are left in for 48 hours to minimize rebleeding and removed at 48 hours to avoid tissue necrosis associated with prolonged placement.

Posterior epistaxis is suggested when bleeding occurs with a properly placed anterior nasal pack. In this case, a posterior pack is necessary with a Foley catheter or commercially available balloon. A standard Foley catheter may be inserted into the nasopharynx, partially inflated with 5 to 7 mL of water, and then pulled anteriorly, creating pressure posteriorly with an additional 5 to 7 mL of water added to the balloon, but caution should be exercised to avoid pressure necrosis. Water, rather than saline, should be used because saline can crystallize and cause problems with balloon deflation. Vaseline gauze should be packed firmly around the catheter anteriorly. Fig. 62.3 shows how the Foley catheter is placed.

The commercially available devices have anterior and posterior balloons. Similar to Foley placement, the device is placed into the nose, inflated, and pulled anteriorly. Once seated, the anterior balloon should be slowly inflated to the point that the patient can tolerate.

If these techniques do not provide successful control, otolaryngologic consultation is necessary. Surgical ligation has been the treatment of choice for intractable bleeding but endovascular embolization has emerged as a treatment alternative. The decision to choose surgery over embolization is influenced by factors such as patient comorbidity, presence of anticoagulation, institutional experience, patient preference, and health care costs. Transnasal endoscopic surgery has advantages in that it visualizes bleeding location, improves the diagnosis of other causes, and is associated with lower health care costs and complications such as blindness. The advantages of embolization include avoiding general anesthesia, improving the diagnosis of vascular pathology, and causing less trauma to the nasal mucosa. In one national survey, patients who underwent endovascular embolization had higher rates of head and neck cancer, hereditary hemorrhagic telangiectasia, and arteriovenous malformation compared with patients who underwent surgical ligation.

Disposition

There has been concern that patients with posterior nasal packs may develop hypoxia as a result of a nasopulmonary reflex. However, there is little evidence to support this theory. Adverse respiratory events are due to a combination of factors such as sedation, underlying cardiovascular or pulmonary disease, and severe obstructive sleep apnea. Most patients with posterior nasal packing can be admitted to a setting with continuous pulse oximetry, but patients with serious comorbidities such as heart disease or obstructive sleep apnea may require a higher level of care.

SIALOLITHIASIS

Stones of the salivary glands occur in 1% of the population. They are usually found in those between 30 and 50 years of age. The most common gland affected is the submandibular (submaxillary) gland, accounting for 80% to 95% of cases. Stones are found less commonly in the sublingual and parotid glands. Sialolithiasis is uncommon in children, occurring in only 3% to 5% of the population.

The exact causative mechanism is unclear, but sialolithiasis is thought to be due to increased viscosity of the saliva and the long upward curvature of the submandibular (Wharton’s) duct. Stasis and inflammation result in precipitation of calcified stones after a nidus of a complex glycoprotein combines with calcium and phosphate. Risk factors include dehydration, diuretic or anticholinergic medications, trauma, gout, and a history of smoking.

Clinical Features

Leading to swelling and pain, obstruction by a sialolith is usually associated with mealtime, when salivary secretion is enhanced. Patients generally present with pain, swelling, and tenderness of the gland. If the gland is infected, the patient may have systemic symptoms, such as fever or chills. The area may be erythematous, with purulence coming from the duct, a condition termed sialadenitis. S. aureus, Streptococcus viridans, S. pneumoniae, and H. influenzae predominate in bacterial infections. Children differ in that they have a shorter duration of symptoms, and their stones present more distally in ducts than those found in adults.

Differential Diagnosis

The differential diagnosis includes salivary gland pathology, lymph node disease, granulomatous process, soft tissue mass, and neoplastic lesion.

Diagnostic Testing

CT without contrast is very sensitive for calculi of all sizes and remains the gold standard, although there is the associated risk of ionizing radiation. Although there have been reports of ultrasonography recognizing up to 90% of stones larger than 2 mm, it does not allow reliable exclusion of small salivary calculi. Both modalities may help identify other causes of inflammation, such as an abscess or cellulitis.

Management

If the stone is palpable, gently massage the gland in an attempt to extract the stone. Additional measures include sialogogues (tart
EPISTAXIS MANAGEMENT: POSTERIOR PACKING WITH INFLATABLE DEVICES

A

1. Insert a 12-Fr Foley catheter through the naris and into the posterior pharynx.
2. Look into the mouth to confirm that the catheter is properly positioned.
3. Inflate the balloon halfway with about 5–7 mL of water.
4. Slowly pull the catheter into the posterior nasopharynx up against the posterior aspect of the middle turbinate.
5. Foley catheter in proper position in the posterior nasopharynx. Inflate the balloon with another 5–7 mL of water.
6. While maintaining traction, place anterior packing with layered gauze. Packing of the opposite side may be required to prevent septal deviation. Place a piece of gauze on the exposed catheter and secure with an umbilical clamp.

B

1. Double-balloon epistaxis catheters have both an anterior and posterior balloon, and some have an integral airway tube. These devices serve as an anterior and posterior pack. They are easily inserted and are often successful in the temporary control of posterior epistaxis in the ED.
2. Insert the lubricated device along the nasal floor as far back as possible. Inflate the posterior balloon halfway with air, apply traction to pull the balloon up against the middle turbinate, and then complete the inflation. Maintain the position of the balloon and then inflate the anterior balloon with 30 mL of air.
3. This patient with posterior epistaxis was successfully treated in the ED and discharged. Historically, most patients with posterior packs were admitted to the hospital; however, the ease and safety of balloon devices allow selected patients to be treated as outpatients. Consider admission for older adults and those with pulmonary or cardiovascular disease.

hard candies to promote glandular secretions), analgesia with antiinflammatory medications, or opioids. When infection is present, antibiotics covering the affected organisms, such as cephalexin, 500 mg qid, or clindamycin, 450 mg tid (in the penicillin-allergic patient), are appropriate.

Disposition

Stones larger than 5 mm or stones located within the gland or in the proximal duct are often resistant to conservative measures. These may require surgical or minimal invasive treatment by an otolaryngologist or oral surgeon.

NECK MASSES

Principles

Neck masses are a relatively common clinical finding, with a multitude of causes. The differential diagnosis can generally be broken down into three categories—inflammatory, congenital, or neoplastic. Children and young adults are more likely to have benign disorders, such as inflammatory or congenital abnormalities, including thyroglossal or branchial cleft cysts. Adult neck masses are more likely to be neoplastic. In general, 80% of nonthyroid neck masses in adults are neoplastic, of which 80% are malignant. In children, however, more than 80% of neck masses are benign. This is often referred to as the rule of 80, or the 80% rule. Risk factors that may predispose patients to ENT malignancies include alcohol and tobacco use, viruses such as herpes, genetics, diet, and excessive exposures to ultraviolet sunlight, dust, or chemicals.

Identifying the parotid and submandibular glands, thyroid cartilage, thyroid gland, and lymph nodes can help distinguish normal structures from other masses (Fig. 62.4). The neck is divided into cervical triangles, with the sternocleidomastoid muscle as the common boundary. The anterior portion is bordered by the midline of the neck, inferior aspect of the mandible superiorly, and anterior border of the neck posteriorly. Lesions of the skin, scalp, oral cavity, oropharynx, hypopharynx, larynx, and tongue may manifest here. The posterior triangle is bordered by the sternocleidomastoid anteriorly, posteriorly by the trapezius muscle, and inferiorly by the clavicle. Lesions in this area may include those from the nasopharynx and metastatic lesions from the lung and gastrointestinal and genitourinary tracts.

Clinical Features

Important associated symptoms include dysphagia, odynophagia, otalgia, stridor, speech disorders, and globus phenomena. Dysphagia, or difficulty swallowing, may be caused by physical obstruction or neurologic disorders. Odynophagia is pain on swallowing and can have a number of causes, such as tonsillitis or carcinoma of the pharynx. In an adult, a sore throat that lasts for several weeks should raise the suspicion of a neoplastic process. Otolgia is pain felt in the ear that may be referred from the larynx, pharynx, or cranial nerves V, IX, or X. Referred ear pain is an ominous sign in adults and should be presumed to be cancer until proved otherwise. Similarly, unilateral OME in adults should be considered nasopharyngeal carcinoma until proven otherwise.

Stridor, specifically inspiratory stridor, is diagnostic of upper airway obstruction. It localizes a lesion to above or at the level of the larynx. In adults, the presence of stridor with a neck mass increases the possibility of carcinoma. Speech disorders, particularly so-called hot potato speech, are suggestive of space-occupying lesions above the oropharynx, such as a peritonsilar abscess. Globus is the symptom of having a lump in the throat. It has occurred in almost everyone at one time or another, is localized to the pharynx, and is often a functional complaint. Hoarseness is a fairly common complaint, with a myriad of causes ranging from viral pharyngitis to laryngeal cancer. Also, similar to the term dizziness, the term hoarseness has many descriptions, including breathiness, muffling, harshness, scratchiness, and unnatural deepening of the voice. Hoarseness lasting longer than 2 weeks should be investigated further. Additional history about the location of the mass, rate of growth, presence of pain, and constitutional symptoms, such as fever, night sweats, and weight loss, are also helpful.

The head and neck examination may identify masses, lesions, mucosal ulcerations or discolorations, and cranial nerve abnormalities. The mass itself should be palpated for location, size, and consistency. Benign lymph nodes are generally mobile, soft, fleshy, and smaller than 1 to 1.5 cm, so any hard nodes larger than 1.5 cm with decreased mobility should be considered abnormal and as warning signs of malignancy.

Differential Diagnoses

Box 62.2 lists common possibilities for the differential diagnosis of neck masses.

Diagnostic Testing

The diagnostic strategy is tailored to results of the history and physical examination. Patients with hoarseness lasting longer than 2 weeks should be referred to an otolaryngologist for a flexible endoscopic examination unless they have developed acute stridor, dyspnea, or sense of acute deterioration. These patients should have otolaryngologic consultation in the ED, and most will need flexible endoscopic examination of the upper airway. In the ED, chest radiography is an initial test to identify possible lung pathology as a source. CT of the neck with contrast is the initial study of choice to delineate significant neck masses better.
Management and Disposition

Most masses in children are inflammatory. Thus, it is a reasonable strategy to start the patient on antibiotics, with a 2-week follow-up. If inflammation is thought to be the cause of the neck mass in an adult, a similar strategy can be used. However, adults need ENT referral if the mass does not resolve in 2 weeks, is enlarging or fixed, or is associated with matted cervical lymph nodes, or if the masses are noted in the parotid or thyroid gland.

AVM, Arteriovenous malformation; EBV, Epstein-Barr virus; HIV, human immunodeficiency virus; HSV, herpes simplex virus.

**KEY CONCEPTS**

- Most cases of AOM resolve spontaneously. Nontoxic children from 6 months to 2 years of age with unilateral AOM and those older than 2 years with unilateral or bilateral AOM may be observed for 3 days to determine whether antibiotics are required. When indicated, amoxicillin is the initial choice for treatment of AOM, 80 to 90 mg/kg per day.
- Otitis externa is treated with topical antibiotic drops. Only fluoroquinolone drops are FDA-approved for use when a tympanic perforation may be present. Necrotizing OE should be considered in immuno-compromised patients who have persistent otitis externa.
- Patients with epistaxis with posterior nasal packing should be admitted to the hospital.
- Bullous myringitis is caused by the usual organisms that cause otitis media.
- Adult patients with AOM should be treated with amoxicillin, 500 mg tid.
- The diagnosis of AOM is made by a bulging TM and signs and symptoms of acute infection.
- Acute hearing loss is most often idiopathic. A 10- to 14-day steroid taper is usually prescribed but is not known to provide benefit.
- Hoarseness or an unexplained neck mass that persists for longer than 2 weeks requires ENT referral.

CHAPTER 62: QUESTIONS & ANSWERS

62.1. Which of the following clinical symptoms is most useful in diagnosing acute otitis media (OM)?

A. Cough
B. Decreased appetite
C. Ear pain
D. Fever
E. Vomiting

Answer: C. Although all the symptoms of acute OM are nonspecific, ear pain appears to be the most useful.

62.2. A 56-year-old man presents with sudden onset of hearing loss in his left ear. He also complains of tinnitus. His neurologic examination is otherwise unremarkable. What should be the next step in the patient’s management?

A. Consult a neurologist.
B. Consult an otolaryngologist.
C. Obtain a head computed tomography (CT) scan.
D. Obtain a magnetic resonance imaging (MRI) scan with gadolinium.
E. Start a steroid taper.

Answer: B. Sudden sensorineural hearing within 72 hours is considered an otolaryngologic emergency. The evaluation and potential treatment options, including steroids, hyperbaric oxygen, and antiviral agents, are best performed in consultation with an otolaryngologist.

62.3. A 30-year-old woman presents with onset of a severe right posterior occipital headache and low-grade fever. Her physical examination reveals an area of erythema and swelling posterior to the right ear and a nonmobile tympanic membrane in that ear. What is the most appropriate next diagnostic step?

A. ENT referral STAT to the operating room (OR)
B. CT scan
C. Lumbar puncture
D. MRI with gadolinium
E. No further diagnostic evaluation necessary

Answer: B. Clinical findings in acute mastoiditis may include fever, headache, otalgia, and posterior auricular erythema and tenderness. Although there are no specific diagnostic criteria, an initial step would be a CT scan to identify mastoid inflammation and possible bony erosion. MRI would be indicated if there is concern for intracranial extension.

62.4. All the following are implicated as risk factors in OM except:

A. Children with cleft palate
B. Daycare attendance
C. Female gender
D. Immunocompromised patient
E. Parental smoking
PART III \ Medicine and Surgery | SECTION ONE \ Head and Neck Disorders

Answer: C. Male gender appears to be a risk factor for middle ear disease, as well as daycare attendance, parental smoking, immunocompromised patients, and children with anatomic abnormalities such as cleft palate or Down syndrome. Breast-feeding appears to be protective.

62.5. An 18-month-old boy returns to the emergency department (ED) 4 days after being diagnosed with left OM. He was prescribed amoxicillin, 90 mg/kg/day, and the parents reported compliance. He has continued ear tugging, fever, and irritability. He is tolerating PO nutrition with no vomiting or diarrhea. Physical examination reveals an alert crying male with oral temperature 101.5°F, heart rate 136 beats/min, and respiratory rate 24 breaths/min. His physical examination is otherwise negative except for severe erythema of the left tympanic membrane, with obscure landmarks and loss of mobility. What is the most appropriate next step in this patient’s management?

A. Admit for intravenous antibiotics.
B. Change therapy to an oral cephalosporin.
C. Draw blood cultures and continue current amoxicillin regimen.
D. Intramuscular ceftriaxone is given.
E. Lumbar puncture is performed.

Answer: D. Otitis media treatment failures at 3 days should receive intramuscular ceftriaxone. Continued use of a failing regimen would not be indicated. The child exhibits no signs or symptoms warranting a lumbar puncture and no immediate criteria for hospital admission.

62.6. A 13-year-old diabetic girl presents with left otalgia, left facial palsy, and fever. Physical examination reveals a left peripheral seventh nerve palsy, intense left otitis externa, diffuse tenderness of the pinna, and mild weakness of the left trapezius muscle. What is the most likely diagnosis?

A. Acute mastoiditis
B. Left temporal brain abscess resulting from left-sided otitis
C. Malignant otitis externa
D. Meningitis
E. Sigmoid sinus thrombosis

Answer: C. Necrotizing (malignant) otitis externa is a result of chronic otitis externa often seen in immunocompromised patients. The facial nerve is the cranial nerve usually affected, but the glosopharyngeal, vagal, accessory, abducens, and trigeminal nerves may also be involved. When otoscopic view permits, granulation tissue in the floor of the external canal at the bone–cartilage junction is characteristic. CT is the imaging technique of choice and is able to indicate bony erosions and abscess formation. Ciprofloxacin is the antibiotic of choice. All the other choices are recognized complications.

62.7. The management of anterior and posterior epistaxis is similar regarding which of the following?

A. Antibiotic requirements after packing
B. Duration of packing
C. Indications for hospitalization
D. Surveillance for secondary complications
E. Value of topical cauterization

Answer: C. Strong evidence for postpacking of antibiotics are lacking in both situations. Anterior packs are left in place for approximately 48 hours, whereas posterior packs may require 3 to 5 days. Patients requiring posterior nasal packs for epistaxis typically need hospitalization for supplemental oxygen and surveillance for pack expulsion with rebleeding, dysrhythmias, bradycardia, aspiration, and stroke.

62.8. Which of the following statements is true regarding inspiratory stridor?

A. It implies a palatal or uveal obstruction.
B. It is diagnostic of tracheal pathology.
C. It is typically accompanied by hoarseness.
D. It localizes a lesion at or above the vocal cord.
E. It may be seen with extremely severe asthma exacerbations.

Answer: D. Inspiratory respiratory distress (stridor) implies an extrathoracic flow obstruction. This may be laryngeal, epiglottis, or pharyngeal. Asthma, emphysema, and aspirated foreign bodies all have expiratory airflow limitations. Inspiratory stridor may or may not directly involve the larynx and may not be accompanied by hoarseness.
Asthma

Richard M. Nowak | Glenn F. Tokarski

Developed nations have higher rates of asthma, which suggests that urbanization and westernization are correlated with increased asthma prevalence. Migrants who move from an area of low asthma prevalence to an area of high asthma prevalence assume increased asthma prevalence, suggesting that environmental factors play a role. Urban areas in the United States (New York City, Los Angeles, and Chicago) have high mortality rates associated with asthma, indicating that poverty and lack of access to medical care may also be major determinants of asthma complications.

Factors that contribute to asthma morbidity and mortality include under-treatment; of acute episodes by emergency clinicians; overuse of prescribed or over-the-counter medications leading to delays in seeking treatment; failure of emergency clinicians to consider previous ED visits, hospitalizations, or life-threatening episodes of asthma; and failure to initiate corticosteroid therapy early in the course of an exacerbation. Cost of asthma care is a barrier to asthma management; African American and Hispanic adults identify costs related to seeking asthma care with a primary care physician and/or an asthma specialist and the cost of asthma medications are significant impediments.

Over-reliance on emergency facilities for all asthma care and lack of access or compliance with ongoing asthma care are other important factors contributing to morbidity and mortality from asthma.

Anatomy and Physiology

Asthma is a complex immunologically mediated condition involving a variety of cellular and airway alterations; airway inflammation and remodeling are the final common pathways that result in bronchospasm and limitation of airflow.

Compared with healthy individuals, patients with asthma show bronchial hyperreactivity (hyperresponsiveness) in response to various environmental and infectious stimuli (eg, methacholine). Allergens (eg, environmental, viruses, occupational) and non-allergic stimuli (eg, exercise, aspirin-induced and menstrual-related asthma) induce bronchoconstriction via release of mediators and metabolic products from inflammatory cells. Edema, inflammation, mucus production, and airway smooth muscle hypertrophy result in bronchoconstriction, airway obstruction, and airflow limitation. Recurrent episodes of airway inflammation result in permanent structural airway remodeling that also contributes to airway obstruction and hyperresponsiveness and decreases in the response to therapy.

Necropsies of patients with fatal asthma reveal grossly inflated lungs that may fail to collapse on opening of the pleural cavities. Histologic examination reveals luminal plugs consisting of inflammatory cells, desquamated epithelial cells, and mucus. Marked thickening of the airway basement membrane, submucosal inflammatory cells, increased deposition of connective tissue,
mucous gland hyperplasia, and hypertrophy of airway smooth muscle are also observed. Reports of slow-onset asthma fatalities reveal greater bronchial eosinophilia and basement membrane thickening when compared with rapid-onset fatal asthma. Reports of rapid-onset fatal asthma describe a greater number of degranulated mast cells and less mucus in the airway lumens, suggesting that terminal events may be dominated by bronchoconstriction without excessive luminal plugging.

Pathophysiology

Evidence that inflammation is a component of asthma physiology was initially derived from autopsy findings in patients with fatal asthma. The airways revealed infiltration by neutrophils, eosinophils, and mast cells and the presence of subbasement membrane thickening, loss of epithelial cell integrity, goblet cell hyperplasia, and mucous plugs. Antemortem bronchial biopsy findings in patients with even mild degrees of asthma also demonstrate inflammatory changes in the central and peripheral airways that correlate with disease severity. Inflammatory and chemotactic cytokines produced by both resident airway and recruited inflammatory cells are identified in bronchoalveolar lavage washings and pulmonary secretions.

Asthma has been divided into allergic and non-allergic types based on the presence or absence of immunoglobulin E (IgE) antibodies to common environmental antigens (pollen, dander, mites) and microbiologic antigens (bacteria, viruses). Exposure to microbes and allergens during childbirth, infancy, and childhood may confer a protective effect against atopy and suppress expression of the asthma phenotype later in life (known as the hygiene hypothesis). Regardless of the asthma type, a common feature is the presence of airway T-helper cells that release cytokines (eg, interleukin [IL]-4, IL-5, and IL-13) that stimulate basophil, eosinophil, mast cell, and leukocyte migration to the airways and enhance IgE production. The result is amplification of the airway

![Fig. 63.1. Asthma prevalence percentages in 2013 by age, sex, and race/ethnicity in the United States. (From Centers for Disease Control and Prevention: Asthma: data, statistics, and surveillance. Available at www.cdc.gov/asthma/asthmadata.htm.)](image)

![Fig. 63.2. Adult asthma prevalence percent in 2010 by education, income, and behavioral risk factors. (From Centers for Disease Control and Prevention: Asthma facts: CDC’s National Asthma Control Program Grantees. Available at www.cdc.gov/asthma/pdfs/asthma_facts_program_grantees.pdf.)](image)
inflammatory response and over time irreversible airway remodeling. These complex cellular interactions clinically manifest as bronchospasm, mucus production, airway edema, and limitation of airflow.

Mast cells and eosinophils contain and release intracellular mediators and cytokines (histamine, prostaglandins, leukotrienes, tumor necrosis factor alpha [TNF-α]) that contribute to prolonged bronchial smooth muscle spasm, edema, and mucus production (Fig. 63.5). Airway epithelial cells are more than a passive barrier and produce pro-inflammatory mediators. Abnormal repair processes may further airway obstruction and contribute to airway remodeling. Nitric oxide produced by airway epithelial cells in the large and small airways and alveoli is a reflection of ongoing airway inflammation. Measurements of fractional exhaled nitric oxide (FENO) are useful for monitoring the response to asthma therapy.10,11

Airway remodeling refers to the persistent structural changes in airways caused by repetitive or chronic airway inflammation. Microscopic remodeling features include epithelial thickening, subepithelial fibrosis, mucus gland metaplasia, increases in airway smooth muscle, angiogenesis, and loss of cartilage integrity. Airway remodeling occurs very early in asthma (childhood) and may precede clinical symptoms. Remodeling features are prominent in patients with severe asthma.12 Basement membrane thickening may be protective by preventing inflammatory cells and proteins from entering the airway submucosa through
a damaged epithelium; simultaneously, this process may be counterproductive by reducing the elasticity of the small airways. Airway remodeling induced by chronic inflammation may lead to the development of chronic irreversible airflow limitation and increased asthma mortality.

Genetics is playing an ever-increasing emerging role in the understanding of asthma pathophysiology. Heritability estimates vary between 35% to 95% for asthma and 30% to 66% for bronchial hyperresponsiveness. The first Genome Wide Association Study (GWAS) identified a novel asthma susceptibility locus on chromosome 17p21 and two large meta-analyses of asthma GWASs identified four gene loci considered robustly associated asthma susceptibility genes. Environmental influences (eg, allergens, pollutants, tobacco, and occupational exposures) are associated with asthma, and the interaction of genetic variability and environmental factors may allow prediction of future disease risk, expression, and severity and response to therapies.

CLINICAL FEATURES

Symptoms
Most patients with acute asthma have a constellation of symptoms, including cough, dyspnea, and wheezing. Cough often begins early in the attack, may be the sole manifestation of the disease in cough-variant asthma and elder patients, and can be associated with sputum production. Although increased airway resistance, diminished flow rates, and increased bronchial hyperactivity are contributing factors, asthmatic patients who come to the ED with nocturnal asthma attacks have disease severity similar to that of other asthmatics. Up to 40% of asthmatic women experience premenstrual worsening of symptoms, which peak 2 to 3 days before menses and are associated with more severe disease; ED visits increase during the preovulatory and perimenstrual intervals.

There are inter-individual differences in the dyspnea perceived by asthmatic subjects for the same level of airway narrowing. Patients with a blunted perception of dyspnea (“poor perceivers”) have more ED visits, hospitalizations, and near-fatal and fatal asthma attacks.

Approximately 80% of patients with asthma have symptoms of rhinitis, whereas 5% to 15% of patients with perennial rhinitis have asthma, and control of sinonasal inflammation can lead to asthma improvement. Overweight (body mass index [BMI] of 25 kg/m² or more) asthmatics have poorer asthma control, higher admission rates, and a greater risk of complications, possibly secondary to a difference in the perception of dyspnea or in response to asthma controller agents. However obesity does not adversely influence the severity or the resolution of an acute exacerbation.

One-third of patients who come to the ED with acute asthma are current cigarette smokers, and these patients (who may have a coexisting chronic obstruction pulmonary disease [COPD]-asthma phenotype) have poorer asthma control and greater acute care needs than lifelong nonsmokers or former smokers. African Americans with acute asthma have lower flow rates and more potentially life-threatening episodes than whites, but they respond equally well to albuterol. There are no racial disparities in inpatient asthma care when comparing whites, blacks, and Hispanics.
Asthma can appear at any age, including the ninth decade, and so wheezing and dyspnea may be mis-attributed by patients and physicians to heart failure, bronchitis, COPD, occupational lung disease, or poor exercise capacity. Older asthmatics (≥55 years old) have higher morbidity and mortality.12

The frequent ED asthma patient tends to be male with social, financial, and addiction problems.17 Also barriers to urgent care and not recognizing the need for provider attention until the need is urgent may contribute to the ED use for asthma.18

Slow-onset asthma with progressive deterioration over a period of at least 6 hours (usually days) occurs in over 80% of cases. This type has a female predominance, is triggered by upper respiratory tract infections, and has an airflow inflammation mechanism that results in a slower response to treatment. Sudden-onset asthma with rapid deterioration in less than 6 hours occurs in less than 20% of cases. This type has a male predominance, is triggered by respiratory allergens, exercise, and psychosocial stress, and has a bronchospastic cause resulting in more severe airway obstruction with a faster response to therapy.

The brief history pertinent to the current exacerbation should include onset and possible triggers (generally the more triggers the worse the clinical status, severity of symptoms especially as compared with previous exacerbations, and other comorbidities—especially those that may be worsened by systemic corticosteroids, such as diabetes, peptic ulcer, hypertension, and psychosis).20,21 All current asthma medications should be noted, including times and amounts recently used, and any potential asthma aggravators, such as aspirin or nonsteroidal antiinflammatory drugs (NSAIDs), beta-blockers (including topical agents used for glaucoma), and angiotensin-converting enzyme inhibitors. Cardioselective and nonselective beta-blocker use increases hospitalizations and ED visits.

Patients with mild acute asthma usually speak in sentences, with moderate asthma they usually speak in phrases, and with severe asthma they usually speak in words. Although alterations in mentation indicate severe asthma, restlessness and agitation do not reliably indicate hypoxia or hypercapnia. Patients who sit upright have severe airway obstruction; cyanosis is uncommon because of the left shift of the oxyhemoglobin dissociation curve produced by respiratory alkalosis.

Tachypnea and tachycardia are associated with severe obstruction, but lower rates do not rule out severe asthma. The respiratory rate correlates poorly with pulmonary function tests (PFTs) and indicates severe obstruction if it is higher than 40 breaths/min. A pulsus paradoxus or inspiratory fall in systolic blood pressure less than 10 mm Hg usually signifies severe disease, but its absence does not exclude it. When present, pulsus paradoxus may disappear with minimal improvement in airflow. Similarly, use of accessory muscles of respiration is not prognostic.

Wheeze does not designate the presence, severity, or duration of asthma. It correlates poorly with the degree of functional derangement and may be absent when maximal effort produces minimal airflow. Physical examination may help to identify such complications of asthma as pneumonia, pneumothorax, or pneumomediastinum.

### BOX 63.1

#### Risk Factors for Death From Asthma

**Asthma History**
- Previous severe exacerbation (intubation or ICU admission for asthma)
- Two or more hospitalizations for asthma in the past year
- Three or more ED visits for asthma in the past year
- Use of more than two MDI short-acting beta-2 agonist canisters per month
- Requiring three or more classes of asthmatic medication
- Current use of or recent withdrawal from systemic corticosteroids
- Difficulty perceiving asthma symptoms or severity of exacerbations

**Social History**
- Low socioeconomic status or inner-city residence
- Serious psychosocial problems
- Alcohol or illicit drug use, especially inhaled cocaine and heroin

**Comorbidities**
- Cardiovascular disease
- Other chronic lung disease
- Chronic psychiatric disease

ACE, Angiotensin-converting enzyme; COPD, chronic obstructive pulmonary disease; GERD, gastroesophageal reflux disease.

### Pulmonary Function Studies

The severity of airflow obstruction cannot be accurately assessed from symptoms and physical examination alone. Because physicians initially tend to underestimate the degree of airway obstruction in acute asthma, routine PFTs should be part of ED assessment and monitoring. The forced expiratory volume in 1 second (FEV₁) from maximal inspiration or the peak expiratory flow rate (PEFR) in liters per second, starting with fully inflated lungs and sustained for at least 10 msec, may be used. Any patient not able to perform PFTs should be considered to have severe airway obstruction.

Although FEV₁ can be adequately measured in most acute asthmatics to meet modified American Thoracic Society performance goals, most assessments in the ED use single-patient-use portable peak flow meters because PEFR is easier to measure. The identical device should be used to assess then reassess an individual patient, and different portable meters should not be used interchangeably. The FEV₁ and PEFR measurements are not interchangeable in assessing acute airway obstruction. Although absolute PFT measurements can be used, the percentage of personal best (optimal) or predicted values are preferable to account for age (now to age 85), sex, and height.

### Blood Gas Analysis

Equilibration of oxyhemoglobin saturation occurs within 3 to 4 minutes of initiation or alteration of supplemental oxygen, and oxygenation status can quickly be monitored using pulse oximetry. Stimulated hyperventilation leads to a fall in the partial pressure of carbon dioxide in arterial blood (PaCO₂). Because airway obstruction increases with resulting hypoventilation, the PaCO₂ normalizes (PFTs 15% to 25% predicted) and then increases (PFTs <15% predicted) with resulting respiratory acidosis. Capnography or a venous blood gas (VBG) will reliably indicate these changes, and an arterial blood gas (ABG) is rarely indicated (unless pulse oximetry cannot be obtained or the clinician has reason to question the capnography or VBG results).

Occasionally, despite improvement in PFT values with bronchodilator therapy, some patients have a transient fall in the partial pressure of oxygen in arterial blood (Pao₂), second to pulmonary vasodilatation and worsening ventilation-perfusion mismatch. Also, capnographic waveform analysis can indicate improvements in airway diameter in acute asthma and has the advantages of being effort independent and providing continuous monitoring.²²

### Other Blood Testing

Leukocytosis is common with acute asthma exacerbation but is not of discriminatory value in detecting acute superimposed pulmonary infection. Corticosteroids and catecholamines demarginate polymorphonuclear leukocytes after 1 to 2 hours, and patients on chronic steroid therapy may have normal or significantly elevated white blood cell counts.

Serum electrolytes are not altered unless the patient is taking corticosteroids or diuretics or has cardiovascular disease and is receiving beta-2 agonist therapy. Frequent albuterol treatments can cause transient hypokalemia, hypomagnesemia, and hypophosphatemia, but this is rarely of clinical significance. The rare asthmatic on chronic theophylline therapy should have a level measured for possible toxicity. In the older asthmatic with cardiovascular comorbidities, measurement of the B-type natriuretic peptide (BNP) level may reveal unrecognized congestive heart failure.

Hyperlactatemia is common in acute asthma and is thought to be secondary to albuterol therapy or the increased work of breathing. However, it is not associated with lower PFTs or more hospitalizations or relapse at 1 week.²² Overall routine testing of the blood in an acute asthma exacerbation is not recommended.

A chest radiograph is of little value in most acute asthma exacerbations and should be restricted to patients with a suspected complicating cardiopulmonary process, such as pneumonia, pneumothorax, pneumomediastinum, subcutaneous emphysema, or congestive heart failure.²⁴ Also, patients who do not respond to optimal therapy and require hospital admission have a higher likelihood of radiographically identifiable, unsuspected, clinically significant pulmonary complications of asthma (15% of cases). The finding of an ultrasound comet-tail sign has high diagnostic accuracy in differentiating acute heart failure-related from COPD/asthma-related causes of acute dyspnea.²⁶

The electrocardiogram (ECG) is selectively helpful in assessing patients with chest pain or a history of significant cardiovascular disease, in whom the asthma attack may be a physiologic stress test. In patients with severe asthma, the ECG may show a right ventricular strain pattern that reverses with improvement in airflow. All patients with severe hypoxemia, and those for whom intubation is contemplated, should also receive cardiac monitoring.

In summary, the severity of airflow obstruction cannot be accurately judged by patients’ symptoms, physical examination findings, and laboratory test results. Serial measurements of airflow obstruction (FEV₁ or PEFR) are key components of disease assessment and response to therapy (Table 63.1).

### Future Monitoring Strategies

Noninvasive monitoring of bronchial inflammation may customize the ED assessment of acute asthma. This may include measurement of biologic biomarkers, such as cytokine profiles and total

antioxidants in the blood, evaluation of leukotriene E4 in the urine, and the monitoring of exhaled pentane, hydrogen peroxide, nitric oxide, or carbon monoxide levels. Of these measurements, exhaled nitric oxide, a marker of airway inflammation, shows the most promise, because studies show that forced expired nitric oxide can be measured in the ED with good reproducibility, and levels measured after 6 hours of care are associated with better asthma control after discharge.26a

**MANAGEMENT**

Subacute lack of asthma control (more than four outpatient visits or more than five short-acting beta-2 agonist prescriptions per year) is associated with increased risk of acute asthma exacerbation. Home management includes increased use of inhaled beta-2 agonists, early administration of systemic corticosteroids (not simply doubling the dose of current inhaled corticosteroids [ICSs]), and specific instructions regarding emergency care.1 The ability to gauge the severity of an attack with use of the ED in a timely manner is important, because patients who wait longer have worse asthma on presentation, more functional limitations, and are more likely to be admitted.27 Emergency medical services providers should provide albuterol inhalation therapy by protocol, and basic emergency medical technicians can be authorized to administer the patient’s own inhaler. Further studies are needed to determine whether paramedics should be trained to administer continuous positive airway pressure ventilation in asthmatics with severe respiratory failure in efforts to decrease tracheal intubation and mortality rates.

The rapidity of reversal of the acute airflow obstruction is directly predictive of the outcome. Effective bronchodilation often results in a decreased need for hospitalization with significant cost savings. As outlined in Table 63.2, the severity of attack as measured by PFTs determines the aggressiveness of the therapy.

**Oxygen Administration**

All patients should receive supplemental oxygen titrated to maintain arterial oxygen saturation more than 90% (>95% in pregnant women and with coexistent heart disease) rather than at predetermined flow rates, because high concentrations of oxygen therapy causes significant increase in PaCO2 in severe acute asthma.28 Humidification of the inspired air-oxygen mixture is not essential, although studies suggest that active airway rehydration should be revisited.

**Adrenergic Medication**

Epidemiologic studies report an association between death and near death from asthma and the frequent use of inhaled beta-2 agonists. The use of more than one canister per month doubles the risk for each additional monthly canister used. Guidelines for chronic use of inhaled beta-2 agonists, however, recommend limited daily use in a rescue-only mode.1

One form of albuterol is a racemic mixture of equal amounts of R and S isomers. Data from animal and human studies suggest that the S isomer with no bronchodilator activity, proinflammatory, is spasmogenic, and induces bronchial hyperreactivity. This

could explain the increased morbidity and mortality rates associated with its regular or excessive use.

Some patients may use at home nonprescription racemic epinephrine (Asthmanefirn, marketed as an alternative to Primatine mist metered-dose inhaler [MDI]) delivered by a handheld electronic ultrasound nebulizer. It may be less effective than albuterol and the U.S. Food and Drug Administration (FDA) has issued a safety alert secondary to adverse reports associated with its use.28

Levalbuterol, the R isomer of racemic albuterol, is available as a preservative-free nebulizer solution (unit doses of 0.31, 0.63, or 1.25 mg) and in a MDI for prevention and treatment of bronchospasm. In chronic asthma, levalbuterol provides a better therapeutic index than the standard dose of racemic albuterol, further fueling the debate on the potential adverse effects of the S isomer of beta-agonists. Clinical studies in acute disease report that levalbuterol on a milligram for milligram basis is a better bronchodilator than similar amounts of R-albuterol delivered with the S isomer in racemic albuterol. The amount and frequency of delivery of levalbuterol and albuterol depend on the initial severity and response to therapy, as shown in Tables 63.2 and 63.3. Patients with more severe obstruction with a poor response to initial therapy should receive higher dosage schedules and continuous administration.29 When patients are stable but require admission to the hospital, it may be possible to administer nebulized levalbuterol at 1.25 mg every 8 hours as opposed to racemic albuterol at 2.5 mg every 4 to 6 hours.

The PFT response to the initial bronchodilator therapy over the initial 15 to 60 minutes is a better predictor of the need for hospitalization than is the severity of an exacerbation. A PEFR variation over baseline of more than 50 L/min and a rate that exceeds 40% of predicted measured at 15 to 60 minutes suggest a good outcome.

Nebulizer Versus Metered-Dose Inhaler and Valved Holding Chamber. An MDI plus a valved holding chamber (“spacer”) provides similar bronchodilation and side effects, even in severe asthma, when compared with nebulization (see Table 63.2). It requires more supervision because some patients have difficulty firing the canister before inhalation, breathing slowly, and holding their breath for 5 seconds, which may explain their infrequent ED use. The MDI with a spacer, however, uses less treatment time and may be more economical.

Intravenous Adrenergic Agonists. Some international asthma guidelines (not United States guidelines) recommend use of intravenous (IV) beta-agonists for severe nonresponsive acute asthma.30 IV albuterol (not available in the United States) is given as a loading dose of 4 µg/kg for 2 to 5 minutes followed by an infusion of 0.1 to 0.2 µg/kg/min, with close monitoring. Evidence to support the use of IV beta-agonists in patients with severe acute asthma is lacking; the potential risks are warranted only when inhaled therapy is not feasible.31 Epinephrine is used cautiously in patients older than 40 years old or those with suspected cardiovascular disease. IV epinephrine titrated to effect (average 1.5 µg/min with a range of 0.5 to 13.3 µg/min) is associated with a low rate of major (3.6% of cases) and moderate or minor adverse events.

Subcutaneous Adrenergic Agents. Subcutaneous use of adrenergic agents does not have an advantage over aerosol delivery. It may be considered in patients who cannot adequately inhale albuterol or who experience severe bronchospasm.

Epinephrine, a mainstay for almost 100 years, has both alpha and beta effects. It can produce tachycardia, hypertension, dysrhythmias, and vasoconstriction. It can be given subcutaneously or intramuscularly (1:1000 solution 0.2 to 0.5 mL every 20 to 30 minutes as needed for three doses). Terbutaline is a longer-acting beta-2 agonist with bronchodilating properties equivalent to those of epinephrine in acute asthma. It can cause skeletal muscle tremor and tachycardia. A 0.25-mg dose can be given subcutaneously every 20 minutes for three doses.

Long-Acting Beta-2 Agonists. Salmeterol is a long-acting (12 hours) beta-2 agonist (LABA) that is an effective additional medication for management of symptoms that are not adequately controlled by regular and adequate doses of effective controller medications, such as ICSSs. Its onset of action is 20 minutes and thus is not a rescue medication. Regular use of this drug without concomitant use of ICSs results in greater hospitalizations and asthma-related deaths, resulting in a black box warning on the package insert.32

Racemic formoterol dry powder and both racemic and single-isomer formoterol solution for nebulization are also LABAs that have onset of action within minutes (similar to albuterol) and maximal effect within 2 hours. These drugs could evolve as acute rescue medications with extended length of action (12 hours) and similar safety profiles.33 The FDA has changed the labeling for LABAs to contraindicate their chronic use in patients of all ages without concomitant use of an asthma controller medication, such as an ICS.34

Corticosteroids

Despite decades of corticosteroid use, controversy persists regarding the types and quantities required to induce a rapid remission, the time needed for drug action, the route of administration, the

existence of dose response effects, and the determination of which patient populations respond to this therapy.

**Systemic Corticosteroids.** Corticosteroids are indicated for all patients with moderate to severe attacks or those experiencing an incomplete response to initial beta-agonist therapy. In addition, early systemic corticosteroids should be considered for patients who are taking oral corticosteroids or ICSs, have relapsed after a recent exacerbation, or have prolonged symptoms. Steroid effects begin within hours in acute asthma and peak at about 24 hours. Use of systemic steroids speeds the resolution of airflow obstruction, reduces the rate of relapse, and may decrease admissions in severe but not in mild to moderate attacks. The PEFR may improve within 2 hours of steroid therapy in those not responding to initial albuterol inhalation.

Studies demonstrate that oral corticosteroids are as beneficial as IV therapy. The initial oral dose is usually 60 mg of prednisone. If IV methylprednisolone is used, the dose is 40 to 80 mg/day in one or two divided doses until the switch to oral therapy or until PEFR reaches 70% of predicted or personal best.

Continuing therapy with oral prednisone or prednisolone is given in an adult dose of 40 to 80 mg/day. Oral dexamethasone can alternatively be prescribed at a dose of 16 mg per day for 2 days. Oral steroid therapy is preferred unless the patient is very ill, is unable to swallow or is vomiting, or is thought to have impaired gastrointestinal transit or absorption.

Side effects of short-term (hours or days) steroid use include reversible increases in glucose (important in diabetics) and decreases in potassium, fluid retention with weight gain, mood alterations including rare psychosis, hypertension, peptic ulcers, aseptic necrosis of the femur, and rare allergic reactions.

**Inhaled Corticosteroids.** Use of ICSs, either alone or in addition to systemic steroids, to treat acute asthma has the potential benefits of reducing systemic side effects, directly delivering medication to the airway, and reducing airway reactivity and edema more effectively. Patients treated with ICSs are less likely to be admitted whether they received systemic steroids or not, and no increased cough or bronchospasm is seen with the use of ICSs. Patients treated with these agents have early improvement in outcomes (<3 hours) because of the topical effects. High doses of ICSs given over hours may be necessary. Evidence suggests that treating both systemically and via airway with corticosteroids in acute disease is more effective than either treatment method alone.

**Corticosteroids and Discharged Patients.** Discharged patients who receive systemic corticosteroids should continue oral outpatient therapy to control disease and prevent relapse. Any need for additional steroids should be determined at follow-up. An acceptable regimen is 40 to 60 mg of prednisone (or equivalent) in single daily dose for a total of 5 to 10 days. Dose tapering to prevent asthma rebound or out of concern for adrenal suppression is unnecessary unless the patient was already receiving systemic steroids or unless a prolonged course of therapy (more than 2 weeks) is deemed necessary. An alternative approach, if compliance or inability to obtain oral corticosteroids is an issue, is to give a single depot dose of dexamethasone 10 mg, triamcinolone diacetate 40 mg, or methylprednisolone 160 mg before discharge.

Patients with acute exacerbations of asthma may be taking insufficient amounts of chronic controller medications based on their symptoms and excessive use of beta-2 agonists. If the patient is not taking oral corticosteroids or ICSs, the addition of inhaled high-dose budesonide (400 µg, two puffs twice per day) to the patient’s regular asthma medications on discharge improves symptoms and decreases relapse by approximately 50% in the ensuing 3 weeks. Thus patients with a history compatible with persistent asthma but not taking any ICS should be given a prescription for one (1- to 2-month supply). Patients already on ICS therapy should continue.

**Corticosteroid-Resistant Asthma.** A small proportion of asthmatics do not respond to high doses of oral and inhaled glucocorticoids. The mechanism of this steroid resistance may be related to abnormalities in the glucocorticoid receptor number or binding properties or may suggest an alternative diagnosis, such as vocal cord dysfunction. These patients are usually receiving alternative therapies, such as cyclosporine, methotrexate, troleandomycin, hydroxychloroquine, azathioprine, gold, intravenous immune globulin (IVIG), or (in the patient with severe allergic asthma) omalizumab.

Anticholinergic drugs available for inhalation therapy include atropine sulfate or methylnitrate, glycopyrrolate, and ipratropium bromide. They are all bronchodilators that override the smooth muscle constrictor and secretory consequences of the parasympathetic nervous system, blocking reflex bronchoconstriction and reversing acute airway obstruction. Ipratropium bromide (Atrovent), a quaternary derivative of atropine, is preferable to atropine or glycopyrrolate.

The maximum effect with inhaled ipratropium is in 30 to 120 minutes, lasting up to 6 hours. Its bronchodilating potency is lower and onset of action slower than those of the beta-2 agonists and should not be used alone for acute attacks. Trials assessing the role of this agent in combination therapy with beta-2 agonists for acute disease have found that ipratropium provides a modest improvement in PFT results and a reduction in hospitalization. These benefits are higher in patients with more severe disease. Treatment recommendations (see Table 63.2) include adding ipratropium (0.5 mg) with the first three albuterol treatments in severe acute asthma (PEFR/FEV1 <40% predicted). The equivalent MDI dose is approximately eight puffs (18 µg/puff) every 20 minutes three times. Ipratropium can be given to anyone, both acutely and at discharge, who has improved with its past use. Ipratropium may be more effective in patients older than 40 years old, should be used in reversing bronchospasm secondary to beta-blocking agents, and might help those in whom psychological factors contribute to their disease.

Inhaled tiotropium bromide is a long-acting (>24 hours) anticholinergic agent (FDA approved for treatment of COPD) that improves symptoms and lung function when added to ICSs with inadequately controlled asthma. Magnesium relaxes bronchial smooth muscle and dilates asthmatic airways in vitro. Mechanisms include calcium channel-blocking properties, inhibition of cholinergic neuromuscular transmission, stabilization of mast cells and T lymphocytes, and stimulation of nitric oxide and prostacyclin. Intracellular magnesium levels are lower in acute asthma and the level correlates with airway reactivity in chronic disease.

There is evidence that IV magnesium therapy for severe attacks can obviate the need for intubation. Magnesium adjunctive administration in severe asthma attacks (FEV1 <25% predicted) improves airflow obstruction and decreases the need for hospital admission. The optimal dose and rates of infusion are unclear, but it is reasonable to administer to adults 2 to 3 g of IV magnesium sulfate over 20 minutes or at rates of up to 1 g/min to patients with severe refractory asthma while continuing aggressive inhalation therapy. IV magnesium therapy is widely used in those with acute severe asthma and life-threatening exacerbations.

Side effects of magnesium infusion are dose related and include warmth, flushing, sweating, nausea and emesis, muscle weakness and loss of deep tendon reflexes, hypotension, and respiratory depression. Inhalation magnesium in acute asthma may also have a role as an isotonic vehicle for nebulized bronchodilator therapy.
in improving the PFT response or it may be nebulized alone for bronchodilation (investigational).

Methyloxanthines

Theophylline is the main oral methyloxanthine used to treat asthma, and a small subset of ambulatory patients may benefit from its chronic administration. The National Asthma Education and Prevention Program (NAEPP) Expert Panel Report- 3 (EPR-3) does not recommend the use of methyloxanthines for acute disease because of lack of demonstrated efficacy and increased adverse events.1 However the British guidelines state that IV aminophylline may benefit a small subset of patients not responding to initial therapy.31

Leukotriene Modifiers

The cysteinyl leukotrienes (LTC4, LTD4, and LTE4) are highly potent mediators of inflammation that play a large role in the pathogenesis of asthma. Zafirlukast (20 mg twice a day) and montelukast (10 mg daily) are rapid-acting, safe, oral asthma controller drugs that are potent and highly selective antagonists of type 1 cysteinyl leukotriene receptors.

Asthmatics generally have elevated levels of leukotrienes, and in acute attacks the amounts in the urine can be markedly increased. The addition of either 7 or 14 mg of IV montelukast (not available in the United States) to standard therapy for acute asthma causes a 15% non–beta-2 mediated increase in FEV1 over placebo. The onset of action is as early as 10 minutes, persisting for 2 hours.38 Oral zafirlukast, when given as adjunctive therapy (20 or 160 mg) for acute asthma, improves PFT results and dyspnea but does not decrease admission rates. Oral montelukast (10 mg) given during acute asthma results in significantly increased PEFR the morning after admission when compared with standard treatment.37 The rapid onset and sustained non–beta-mediated bronchodilating effects of these medications may help manage acute disease.

Other and Future Therapies

In patients without dehydration or hypovolemia, vigorous administration of fluids does not clear airway secretions. Mucolytics may worsen cough or airflow obstruction, and chest physical therapy is not beneficial. Sedatives are contraindicated in acute disease because of their respiratory depression.

Bacterial, chlamydial, and mycoplasmal respiratory tract infections infrequently contribute to acute asthma. Antibiotics should generally be reserved for patients with fever, purulent sputum, pneumonia, or evidence of bacterial sinusitis, to prevent inappropriate prescription of antibiotics for acute asthma.

Neurokinin antagonists, inhaled loop diuretics (furosemide in acute attacks), and lidocaine may inhibit neurogenic inflammation. Infused BNP and enoximone (a phosphodiesterase III inhibitor) can cause significant bronchodilation.38 Specific cystokine antagonists, agonists, inhibitors of T-cell function, selective inducible nitric oxide synthetase inhibitors, and possibly gene directed therapies may become novel treatments.

There are currently biologic therapies available for the management of chronic asthma. Omalizumab, a recombinant humanized monoclonal anti-IgE antibody, is indicated for the treatment of severe allergic asthma.39 It has been shown to control symptoms in severe chronic asthmatic and may be an alternative for patients with poor compliance to ICS therapy.40-42 Benralizumab, an antiinterleukin 5 receptor α monoclonal antibody, when given in the ED to severe nonresponding patients decreases future hospitalizations.42

The use of percutaneous vagal nerve stimulation for acute asthma has been reported.43 Lastly, the use of rescue therapy with an inhaled combination of a rapid-onset beta-agonist and a corticosteroid might provide both bronchodilation and self-titrated antiinflammatory therapy.

SPECIAL SITUATIONS

Pregnancy

Asthma complicates 4% to 8% of pregnancies, and 27% of pregnant women with asthma have at least one ED visit or hospitalization during pregnancy.44 The effect of pregnancy on asthma is unpredictable. Knowledge of a pregnant patient’s baseline asthma severity is important to predict the risk of severe exacerbation during pregnancy. Asthma exacerbation rates and hospitalizations are directly proportional to the degree of asthma control (NAEPP guidelines1) and pregnant patients with severe asthma have an exacerbation rate of 52% and a hospitalization of 27%.45 Obesity and female fetal sex are associated with an increased risk of exacerbation.46 Maternal and neonatal outcome are excellent in patients with mild or moderate asthma; severe asthma during pregnancy is associated with gestational diabetes and delivery before 37 weeks.47

The hyperventilation of pregnancy is compensated for by a metabolic acidosis. Typical pregnant patients have ABGs with a pH of 7.40 to 7.45, PO2 of 106 to 110 mm Hg, and partial pressure of carbon dioxide (PCO2) of 28 to 32 mm Hg; therefore a normal PCO2 actually represents hypercarbia. Maternal hypoxia quickly results in fetal hypoxemia. PEFV remains unchanged during pregnancy, and monitoring in the ED is strongly recommended. Monitoring of FENO has also been demonstrated to reduce asthma exacerbations in pregnant women.47

The smallest amount of medication needed to maintain the pregnant asthmatic in the mild severity range is recommended. Acute exacerbations should be treated as in any nonpregnant patient. Pregnant asthmatics have been observed to be less likely to receive systemic corticosteroids than non-pregnant asthmatics in the ED.48 However, oral and IV steroids are safe during pregnancy and should be administered in a manner similar to non-pregnant patients. ICSs are not associated with adverse perinatal outcomes and are recommended for all pregnant patients with asthma (budesonide is preferred). Inhaled beta-2 agonists, ipratropium, magnesium sulfate, cromolyn, theophylline, and leukotriene antagonists are safe.49 Heliox and use of NPPV have been reported in pregnant women with critical asthma syndromes (CASs) without negative effect. Oxygen saturation should be maintained at 95% or more. Intensive care unit (ICU) admission and mechanical ventilation are recommended as in any other patient, with the caveat that a PCO2 of 40 to 45 mm Hg represents early respiratory failure in the pregnant patient. Refractory severe or uncontrolled asthma may be improved by delivery. Fetal monitoring is recommended for third-trimester ED patients with moderate or severe asthma exacerbations. Acute asthma attacks are rare in labor likely due to endogenous steroid production. There are no contraindications to any asthma medication in the breast-feeding patient.

Aspirin-Exacerbated Respiratory Disease

Aspirin-exacerbated respiratory disease (AERD) was first described more than 100 years ago. Clinically, AERD includes the tetrad of nasal polyps, eosinophilic sinusitis, asthma, and sensitivity to cyclooxygenase (COX)-1 inhibitor drugs (eg, aspirin).49 NSAIDs also precipitate AERD. AERD is a common precipitant of life-threatening asthma; one survey notes that 25% of asthmatics who require mechanical ventilation have AERD.
Clinically, most patients with AERD are females who develop symptoms in the third decade (average age of onset is 34 years old), frequently after a viral respiratory illness. A previous history of asthma or allergic rhinitis may be noted, but many patients have no prior respiratory disease. The initial phase manifests as nasal congestion that progresses to eosinophilic rhinosinusitis and nasal polyposis; bronchial asthma and sensitivity to aspirin (acetylsalicylic acid [ASA]) and NSAIDs then results. After ingestion of aspirin or a nonsteroidal drug, acute asthma symptoms occur within 3 hours, usually accompanied by profuse rhinorrhea, conjunctival injection, periorbital edema, and occasionally a scarlet flushing of the head and neck.

The pathogenesis of AERD is detailed in Figure 63.6. ASA inhibits COX, of which two isoforms have been identified. COX-1 produces prostaglandins that are involved in normal physiologic maintenance of renal function, gastric mucosal integrity and hemostasis, and inflammatory states. COX-2 is not expressed in normal physiologic circumstances but produces prostaglandins only in response to inflammatory stimuli. COX is necessary for the production of prostaglandin E2 (PGE2) in mast cells and eosinophils. PGE2 has a stabilizing effect on these cells via blockade of the production of prostaglandin E2 (PGE2) in mast cells and eosinophils. Cytokines and staphylococcus, super-antigens in the airways, amplify the inflammatory response. Nasal topical and systemic corticosteroids remain the cornerstone of therapy for AERD, and many patients benefit from agents that block synthesis of leukotrienes (eg, zileuton) or specific leukotriene receptors (eg, zafirlukast, montelukast). Desensitization with slowly increased doses of oral aspirin may be used when aspirin avoidance is not possible (eg, in patients with cardiovascular disease).

COX-2 inhibitors have the advantage of inhibiting inflammation without renal, gastrointestinal, or hematologic side effects. AERD is not reported after administration of COX-2 inhibitors. These agents provide a potentially safe alternative for treatment of inflammatory conditions in patients with AERD.

Acetaminophen is a poor COX inhibitor. Most patients with AERD can tolerate up to 500 mg of acetaminophen safely, but 28% to 34% experience mild respiratory reactions when administered 1000 to 1500 mg. Reactions to acetaminophen tend to be milder than those to NSAIDs.

Exercise-Induced Asthma

Exercise-induced bronchoconstriction has been recognized since the first Olympic Games. It occurs in 5% to 20% of the general population, 30% to 70% of elite winter and summer endurance athletes, and up to 90% of patients with persistent asthma. Atopy is strongly associated with exercise-induced asthma (EIA), and up to 40% of patients with allergic rhinitis have EIA. Clinically, EIA is usually preceded by 3 to 8 minutes of exercise. Peak symptoms usually occur 8 to 15 minutes after exercise is complete and...
then begin to remit spontaneously; recovery occurs within 60 minutes.

The key stimulus is felt to be airway dehydration resulting from increased ventilation, resulting in an increase in the osmolarity of the airway lining fluid. The increased osmolarity is felt to trigger release of mediators (histamine, leukotrienes, prostaglandins) from airway inflammatory cells, resulting in smooth muscle contraction and airway edema.\(^5\) Another exercise-specific factor is autonomic deregulation associated with prolonged high-intensity physical training. The predominantly parasympathetic drive of athletes (evidenced by low heart rates) may also increase bronchomotor tone and increase the risk of EIA.

Prophylaxis for EIA includes environmental measures (face mask or nasal breathing to allow warming and humidification of cool dry air, pre-exercise warm-up, and avoidance of known allergens) and medications. Inhaled glucocorticoids are strongly recommended and a short-acting inhaled beta-2 agonist used 5 to 10 minutes before exercise is effective in preventing exercise induced bronchoconstriction (however the regular use of inhaled beta-2 agonist may lead to tolerance and a decrease in their effects during exercise).\(^5\) LABAs in combination with inhaled glucocorticoids are useful when low doses of inhaled glucocorticoids are ineffective. Pretreatment with cromolyn, leukotriene antagonists (montelukast), and inhaled parasympatholitics is also effective.

**Perimenstrual Asthma**

Perimenstrual asthma affects up to 40% of asthmatic women yet receives little emphasis in asthma treatment guidelines. The ratio of female-to-male asthma prevalence increases dramatically after puberty, and health care for asthma increases in the perimenstrual phase. Perimenstrual asthma is associated with high BMI, low forced vital capacity (FVC) percentage predicted, and higher rates of gastroesophageal reflux disease and is common in women with severe and poorly controlled asthma.\(^2\) Perimenstrual reductions in PEFRs of 35% to 80% are reported. Fluctuations in estrogen and progesterone levels are postulated as causal factors.\(^3\) Estradiol inhibits eosinophil degranulation and suppresses leukotriene activity; estrogen withdrawal in the luteal phase may enhance these actions. Progesterone may also have bronchodilator and antiinflammatory activity, and the rapid decline in progesterone levels before menstruation may contribute to increased bronchospasm. Beneficial therapies for perimenstrual asthma include leukotriene antagonists, LABAs, and oral contraceptives.

**Critical Asthma Syndromes**

Patients with severe asthma represent about 5% to 10% of all asthmatics yet consume excessive health care resources. The European Respiratory Society/American Thoracic Society guidelines define severe asthma as that requiring treatment with high dose ICS and LABA or leukotriene modifier/short-acting beta-2 agonist for at least 80% of the previous year to preventing it from becoming “uncontrolled” or which remains “uncontrolled” despite this therapy. Uncontrolled asthma is defined as one of the following:

1. Poor symptom control (ACQ consistently >1.5, ACT <20 (or “not well controlled” by NAEPP/Global Initiative for Asthma guidelines)
2. Frequent severe exacerbations: Two or more bursts of systemic corticosteroids (>3 days each) in previous year
3. Serious exacerbations: At least one hospitalization, ICU stay, or mechanical ventilation in the previous year
4. Airflow limitation: After appropriate bronchodilator, withhold FEV\(_1\) <80% predicted (in the face of reduced FEV\(_1\)/FVC defined as less than the lower limit of normal)
5. Controlled asthma that worsens on tapering of these high doses of ICS or systemic corticosteroids (or additional biologics)

**European Respiratory Society/American Thoracic Society Definitions of Severe and Uncontrolled Asthma**

**Severe asthma** for patients 6 years old and older is defined as:

- Asthma which requires treatment with guidelines suggested medications for Global Initiative for Asthma steps 4 to 5 asthma (high-dose ICS and LABA or leukotriene modifier/theophylline) for the previous year or systemic corticosteroids for ≥50% of the previous year to preventing it from becoming “uncontrolled” or which remains “uncontrolled” despite this therapy.

**Uncontrolled asthma** is defined as one of the following:

- Poor symptom control (ACQ consistently >1.5, ACT <20 (or “not well controlled” by NAEPP/Global Initiative for Asthma guidelines)
- Frequent severe exacerbations: Two or more bursts of systemic corticosteroids (>3 days each) in previous year
- Serious exacerbations: At least one hospitalization, ICU stay, or mechanical ventilation in the previous year
- Airflow limitation: After appropriate bronchodilator, withhold FEV\(_1\) <80% predicted (in the face of reduced FEV\(_1\)/FVC defined as less than the lower limit of normal)
- Controlled asthma that worsens on tapering of these high doses of ICS or systemic corticosteroids (or additional biologics)

ACQ, Asthma Control Questionnaire; ACT, Asthma Control Test; FEV\(_1\), forced expiratory volume in 1 second; FVC, forced vital capacity; ICS, inhaled corticosteroid; ICU, intensive care unit; LABA, long-acting beta-2 agonist; NAEPP, National Asthma Education and Prevention Program.

Clinical Approach to the Critically Ill Asthmatic

The critically ill asthmatic appears agitated (hypoxemic), assumes an upright position, and appears to be in severe respiratory distress. Tachypnea, diaphoresis, and accessory muscle use are evident. Speech is fragmented into single or short bursts of syllables or words. Absence of wheezing indicates severe expiratory obstruction and minimal air movement. Peak expiratory testing is difficult for the patient to perform but when possible indicates severe expiratory obstruction. Alterations in consciousness and bradypnea indicate hypercarbia and impending respiratory arrest.

No laboratory markers identify critically ill asthmatics. Measurement of lactic acid is not recommended in the critically ill asthmatic. Elevated lactic acid levels are common in patients receiving beta-2 agonist therapy and are not commonly associated with metabolic acidosis. Hyperlactemia occurs even in ventilated and paralyzed asthmatics thus does not necessarily represent respiratory muscle fatigue. An elevated lactic acid level is not predictive of respiratory failure in critically ill asthmatics and should not be interpreted as a poor prognostic indicator. Serial peak flow measurements are the best indicator of severity and response to therapy.

Attempts to abort the episode include continuously nebulized beta-2 and anticholinergic agents (see Table 63.2). If parenteral adrenergic therapy is desired, terbutaline is preferred because of its beta-2 selectivity. IV magnesium sulfate or beta-agonists (where available) may be of benefit. Oral prednisone 60 mg or IV methylprednisolone 125 mg should be administered. The potential role of cytokine and TNF-α antagonists, such as etanercept and infliximab, is unclear. Goluminab, a monoclonal antibody to TNF-α possesses an unfavorable risk-benefit profile and has not been found to be clinically useful. Studies using monoclonal antibodies against IL-5, IL-4, and IL-13 are ongoing, but definitive benefit is lacking.

Helium is an inert gas with one-eighth the density of nitrogen. When 60% to 80% helium is blended with 20% to 40% oxygen, the resulting gas mixture (heliox) has a threefold reduction in density compared with air. Heliox reduces the resistance associated with gas flow through airways with non-laminar flow and reduces respiratory muscle work; it also increases the diffusion of carbon dioxide and may improve alveolar ventilation. Although heliox is not intrinsically therapeutic, it may decrease the work of breathing long enough to abort intubation by carrying bronchodilators to the distal airways and allowing antiinflammatory agents time to achieve their effects. When heliox was compared to oxygen to drive nebulized delivery of beta agonist therapies, a 17% increase in PEFR and a lower rate of hospitalization was observed. Patients with severe asthma receiving heliox nebulization of beta-2 agonists have significant increases in PEFR and other PFTs compared to those mild-moderate asthma. Heliox has not been demonstrated to decrease the need for intubation in severe and resistant asthma. It is administered by nonrebreather mask and can be used with mechanical ventilation. Considerations for heliox include cases of severe airflow obstruction (PEFR <30% predicted and a rapid onset of symptoms within 24 hours), a history of labile asthma or previous intubation, and inability to be adequately mechanically ventilated.

NPPV may benefit carefully selected patients with severe and resistant asthma (see Chapter 2). Continuous positive airway pressure improves oxygenation and reduces respiratory muscle fatigue by increasing functional residual capacity and lung compliance and supplying some of the inflating pressure required during inspiration. Biphasic positive airway pressure (BiPAP) provides continuous positive airway pressure but delivers higher pressure during inspiration than expiration. BiPAP allows speech and reduces the need for sedation. Nebulized bronchodilators can be delivered through the BiPAP circuitry. BiPAP is well tolerated by children with status asthmaticus and may decrease the need for intubation and mechanical ventilation. BiPAP may decrease the need for hospitalization, intubation, and ICU/hospital length of stay in adults with status asthmaticus. However, there is limited evidence to routinely recommend NPPV in patients with respiratory failure from severe asthma exacerbations. BiPAP is not a substitute for endotracheal intubation and mechanical ventilation. Recommendations for BiPAP are conditional—a trial of BiPAP before intubation and mechanical ventilation should be considered in select patients. Patient considerations include alert mental status and intact airway reflexes. Providers should be familiar with BiPAP use in other medical conditions (eg, COPD, congestive heart failure), and ICU admission is mandatory. Intermittent ABG monitoring during BiPAP identifies nonresponders.

Ketamine is an IV dissociative anesthetic with potent bronchodilator effects. Case reports suggest benefit when used in acute asthma, but only a single randomized controlled trial evaluating its use in children with acute asthma exacerbations has been performed and no significant benefit was reported. At present, ketamine is not recommended for therapy of acute asthma in the nonintubated patient.

Endotracheal intubation and mechanical ventilation is required in 2% of all asthma exacerbations and 10% to 30% requiring ICU admission. Indications for intubation include coma, altered consciousness, cardiac or respiratory arrest, paradoxical breathing pattern, refractory hypoxemia, and failure of NPPV. Some authors recommend threshold levels for intubation based on ABG results, but there is no evidence that ABG results provide better guidance regarding need for intubation than does overall clinical assessment.

Orotracheal rapid sequence intubation (RSI) with induction agents and muscle paralysis is preferred (see Chapter 1). A large endotracheal tube (28.0 mm for adults) will facilitate airway suctioning, mucous plug removal, and bronchoscopy. Ketamine (1 to 2 mg/kg) is the preferred agent for induction in RSI of the asthmatic patient because of its bronchodilatory and sympathetic stimulatory properties. Succinylcholine (1.5 mg/kg) or a competitive neuromuscular blocking agent, such as rocuronium (1 mg/kg), can be used for intubation paralysis. Alternatively, propofol (1.5 to 2 mg/kg) offers rapid-onset deep sedation and also possesses bronchodilating properties, but its vasodilatory effects may cause hypotension, especially in the volume depleted asthmatic. Continued deep sedation with propofol, a long-acting benzodiazepine (eg, lorazepam) or an opioid that does not release histamine (eg, fentanyl) usually avoids the need for muscle paralysis and can improve patient comfort. After emergent intubation has been accomplished, care must be taken to avoid hyperventilation.

A ventilator strategy providing adequate oxygenation and ventilation while minimizing hyperinflation, high airway pressure, barotrauma, and systemic hypotension must be instituted. Priority must first be given to decreasing hyperinflation—not correcting hypercarbia and respiratory acidosis. The technique of permissive hypercapnia is common (see Chapter 2). Airway pressure is kept low by providing low tidal volumes (6 to 8 mL/kg), thus preventing excessive increases of intrinsic positive end-expiratory pressure (“auto-PEEP”), stacking of ventilations, and barotrauma. Low ventilation rates (below 10 breaths/min) and high inspiratory flow rates (above 60 L/min) provide prolonged time for expiration. Oxygenation is maintained by use of a high fraction of inspired oxygen (Fio2). Hypercarbia and respiratory acidosis (pH maintained at 7.15 to 7.2 with sodium bicarbonate) is tolerated. Adjunctive therapies (IV hydration, inline beta-2 agonists and anticholinergics, IV corticosteroids, and possibly magnesium) to decrease airway pressure and airway obstruction are delivered simultaneously.
Continuous capnography is advisable. Moderate levels of hypercapnia are well tolerated and have few deleterious effects. Elevated carbon dioxide levels have vasodilatory effects on cerebral vessels. Cerebral blood flow reaches its maximum at a PaCO₂ level of 120 mm Hg, which may increase intracranial pressure. Although there is no consensus on what constitutes a safe level of hypercapnia, PaCO₂ levels above 100 mm Hg should be avoided. Hypercapnia can decrease cardiac contractility and produce cardiovascular collapse; thus permissive hypercapnia should be supplemented by generous repletion of intravascular volume through IV fluids.

Neuromuscular blocking agents should be used only in cases in which deep sedation with adequate analgesia fails to provide sufficient relaxation for successful mechanical ventilation (see Chapter 1). Myopathy attributed to the use of neuromuscular blocking agents (and corticosteroids) is correlated with the dose and duration of administration of these agents. Because corticosteroids are an essential element of therapy for the critically ill asthmatic, the use of neuromuscular blocking agents should be avoided. Complications of mechanical ventilation in the asthmatic patient include hypoxemia, hypotension, nosocomial infections, and barotrauma. Hypotension is almost uniformly secondary to increased intrathoracic pressure with a subsequent decrease in venous return and cardiac output. Slowing the rate of mechanical ventilation or removing the patient from the ventilator for a short time (20 to 30 seconds) allows more time for expiration, thereby decreasing intrathoracic pressure. Volume depletion and medication effects (eg, narcotic sedative agents) are other potential explanations for hypotension. Pneumothorax should be considered whenever sudden deterioration occurs or when hypotension is accompanied by a significant rise in peak inspiratory ventilator pressures. Although complications may occur, the use of mechanical ventilation in critically ill asthmatics is associated with low morbidity and mortality.

If the intensively treated, intubated critically ill asthmatic continues to have elevated airway pressures, persistent hypoxemia, and continued bronchospasm, general anesthetic agents should be considered. IV anesthetic agents are more practical to use in the ED. Data supporting the use of IV ketamine and propofol is sparse, but these agents have bronchodilatory effects and may be of benefit in this situation.

The American Heart Association recommendations for CPR in asthmatics indicate no difference from other cardiac arrest situations. However, the technique of external lateral chest compression may be of benefit. Chest compression is delivered by bilateral squeezing of the lower chest walls immediately after end inspiration occurs. Compressions delivered too early (ie, during inspiration) may increase airway pressure and result in barotrauma. Allowing more time for exhalation during CPR ventilation is paramount.

Unrecognized barotrauma may cause cardiac arrest. Rapid bedside ultrasound should be used to identify occult pneumothorax and reveal nonpalpable cardiac contractions. Empirical bilateral tube thoracostomy should be performed if unexplained cardiac arrest occurs, especially in the context of dramatic increases in peak inspiratory pressure. IV epinephrine is a logical agent in the setting of cardiopulmonary arrest, because it has inotropic, chronotropic, and bronchodilatory properties. Isoproterenol, a pure beta-agonist, may increase heart rate and provide bronchodilation but decreases coronary perfusion pressure. Extracorporeal membrane oxygenation (ECMO) may be indicated for severe asthma refractory to conventional therapies.

**DISPOSITION**

Asthmatic patients discharged from the ED have rates of relapse that vary from 11% over 3 days to 45% at 8 weeks. The relapse risk increases in those with numerous asthma-related ED visits within the previous year, with more outpatient medications, and with longer duration of symptoms before the ED visit. Other studies find similar out-of-control indices predicting relapse but have also included insufficient improvement in PFTs with hospital-based treatment for an attack.

Patients requiring extended care who are without life-threatening exacerbations, pregnancy, or complications of asthma can generally be treated in an observation unit with 8-week outcomes equal to those admitted and with significant cost savings. The ability to predict discharge from the observation unit can be assessed by the PEFR response to the third beta-2 agonist treatment (PEFR >40% predicted is often associated with successful observation unit discharge). Patients prefer observation unit treatment of acute attacks over routine inpatient care. Table 63.4 summarizes disposition guidelines.

Asthma exacerbation does not end on discharge; airway inflammation and peripheral obstruction may take hours to days to resolve. Patients are likely to need continued beta-2 agonist rescue therapy, and they should demonstrate the correct use of their inhalers. If the patient is having difficulty coordinating the canister activation with inhalation, a breath-activated inhaler or spacer device can be prescribed or the need for a home nebulizer discussed. A patient using a portable, preloaded, multidose dry powder inhaler must be able to inhale from the mouthpiece in a rapid and forceful inhalation to total lung capacity.

Patients receiving ED systemic corticosteroids should continue these orally for 5 to 10 days. If the patient was not using controller medications before the acute visit and has characteristics of persistent asthma (symptoms or rescue therapy more than twice per week, interference with sleep more than twice per month, activity limitation caused by asthma or exacerbations requiring oral corticosteroids more than once in the past year), moderate-dose ICSs or a combination ICS and LABA should be started. A less preferred option is to prescribe a leukotriene modifier (eg, zafirlukast 20 mg twice a day or montelukast 10 mg daily) to decrease relapse and improve asthma control.

Patients should contact their physician for asthma-related problems within the following 3 to 5 days and should make a

CDU, Clinical decision unit; FEV₁, forced expiratory volume in 1 second; PEFR, peak expiratory flow rate.
The asthma patient can be provided written education about discharge medications, medication adjustment if the condition is not improving (such action plans are not often created and when done are often inadequate) and a peak flow meter for daily measurements, especially for those who have difficulty perceiving airflow obstruction or who have symptoms of worsening asthma. At a minimum, focused education should address the need for follow-up and for understanding the difference between controller and rescue medications and their use. Smoking asthmatics have more respiratory symptoms, lower lung function, and more parenchymal abnormalities noted on chest computed tomography, so smoking cessation should be discussed.

**KEY CONCEPTS**

- Inhaled and systemic steroid medications are effective in controlling airway inflammation and have important roles in management of asthma exacerbations.
- Inhaled bronchodilators and systemic corticosteroids remain as the mainstays of management for most acute asthma exacerbations.
- Theophylline is the main oral methylxanthine used to treat asthma, and we do not recommend its use for acute disease because of lack of demonstrated efficacy and increased adverse events.
- Critical asthma syndromes (CASs) require rapid identification. Treatment must be aggressive and may use strategies not used in mild to moderate exacerbations, such as infusion of magnesium sulfate, use of noninvasive ventilation, and endotracheal intubation.
- Ventilator management in the intubated asthmatic is critical and includes lower tidal volumes (6 to 8 mL/kg) and low respiratory rates, often less than 10 per minute.
- A normal partial pressure of carbon dioxide (P<sub>CO</sub><sub>2</sub>) in a pregnant patient represents hypercarbia.
- Elevated lactic acid levels are common in critically ill asthmatics and do not reflect deterioration or a poor prognosis.
- ED management of acute asthma is expanding (up to 24 hours) as more non-critically ill asthmatics are treated in observation units.
- Integration of discharged patients with acute asthma into chronic management strategies to prevent relapse requires that asthma patients’ physicians be familiar with controlling medications, such as ICSs and leukotriene modifiers.

CHAPTER 63: QUESTIONS & ANSWERS

63.1. A 33-year-old woman presents with a first-ever episode of shortness of breath, nonproductive cough, and wheezing. She had been previously healthy but experienced a mild upper respiratory infection 1 month ago, followed by chronic nasal congestion, conjunctival infection, rhinorrhea, and decreased sense of smell. This episode of cough and wheezing started 2 days ago. Inspection reveals a healthy appearing woman with mild respiratory distress: temperature, 97.5°F (36.4°C) oral; blood pressure, 110/70 mm Hg; respiratory rate, 24 breaths per minute; and oxygen saturation, 95%. Physical examination is remarkable for diffuse moderate expiratory wheezes. Chest radiograph is negative. What is the most likely diagnosis?

A. Aspirin-exacerbated respiratory disease (AERD)
B. Atypical pneumonia
C. Bronchitis
D. Maxillary sinusitis
E. Pulmonary aspergillosis

Answer: A. This is a classic adult-onset sequence presentation for AERD. Aspirin sensitivity and periodic asthma flares typically follow this apparent upper respiratory infection–induced cycle. Clinically significant sinusitis might be expected to show facial pain/tenderness with fever. Bronchitis may present with bronchospasm, but the nasal and ocular symptoms do not fit. Pulmonary aspergillosis would likely occur in an immunosuppressed patient or very chronic asthmatic.

63.2. Periodic asthma flares may be precipitated by which of the following?

A. Increased production of prostaglandin E₂ (PGE₂)
B. Falling leukotriene levels
C. Falling progesterone levels
D. Rising estrogen levels
E. Thyroid hormone fluctuations

Answer: C. Menstrual-induced asthma is likely triggered by falling progesterone levels just prior to menstruation. Estrogen may likewise exert a salutary bronchodilating effect. Elevated levels of the inflammatory mediator leukotriene are the hallmark of chronic asthma. Cyclo-oxygenase inhibition by nonsteroidal anti-inflammatory drugs (NSAIDs) and falling PGE₂ levels may explain part of the aspirin-induced asthma syndrome.

63.3. A 30-year-old woman with a history of asthma presents with a typical asthma flare that has progressed slowly over 16 hours. Which of the following is true?

A. Airway obstruction is probably more predominant than airway inflammation.
B. Most cases of asthma exacerbations in adults have a much more rapid and abrupt onset.
C. Response to treatment would be expected to be rapid.
D. Steroids are less likely to be helpful.
E. The episode was likely triggered by an upper respiratory infection.

Answer: E. Slow-onset asthma typically occurs in females. This phenotype represents 80% of cases. There is a primary inflammatory mechanism, and response to treatment is slower.

Abrupt-onset asthma more typically occurs in males and is bronchospastic, exercise or stress induced, and more rapidly responsive to treatment.

63.4. Which of the following is a risk factor for sudden death from asthma?

A. A hospitalization for asthma in the past year but not within the past 30 days
B. An emergency department (ED) visit for asthma in the past year but not within the past 30 days
C. Current use of systemic corticosteroids
D. Patient perception that the current exacerbation is very severe
E. Use of over-the-counter medications

Answer: C. Risk factors for sudden death are current or recent corticosteroid use, ED or hospitalization within the past 30 days, more than two hospitalizations for asthma in the past year, more than three ED visits for asthma in the past year, using more than two beta-agonist canisters per month, previous intubation or intensive care unit (ICU) visit, and difficulty perceiving symptoms or their severity.

63.5. A 23-year-old man with known severe asthma presents with an acute asthma flare over 2 hours. Physical examination reveals a well-developed man in marked respiratory distress. Heart rate is 120 beats per minute, oxygen saturation is 90%, respiratory rate is 26 breaths per minute, blood pressure is 140/92 mm Hg, and oral temperature is 98.7°F (37.2°C). Current medications are albuterol metered-dose inhaler (MDI) and fluticasone inhaler 300 µg twice daily. What therapy is recommended for this acute flare?

A. Albuterol 2.5 mg nebulized, methylprednisolone 125 mg intravenously, and magnesium sulfate 3 g intravenously
B. Epinephrine infusion at 5 µg per minute
C. Ipratropium 500 µg nebulized × three doses with methylprednisolone 125 mg intravenously
D. Methylprednisolone 125 mg intravenously with salmeterol nebulized via continuous nebulization
E. Terbutaline 0.25 mg subcutaneously, ipratropium 500 µg nebulized, and methylprednisolone 125 mg intravenously

Answer: A. Short-acting inhaled beta-agonists, with or without anticholinergics (ie, ipratropium), are the cornerstone of acute asthma management. Corticosteroids are indicated in any moderate or severe flare. Oral steroids are as efficacious as intravenous (IV) steroids if the patient can take oral medications. Magnesium sulfate may obviate the need for intubation in severe cases. Salmeterol is a slow-onset, long-acting beta-2 agonist (LABA) not indicated in acute asthma management.

63.6. What is the medication combination of choice for the rapid sequence induction of an asthmatic?

A. Etomidate/succinylcholine
B. Ketamine/succinylcholine
C. Midazolam/pancuronium  
D. Propofol/rocuronium  
E. Thiopental/succinylcholine  

**Answer:** B. No choice is contraindicated. Ketamine is the sedative of choice because of its bronchodilatory effect. Propofol may have this same benefit, although less profound. Thiopental releases histamine, and etomidate does not bronchodilate. Succinylcholine releases trace amounts of histamine, but this is not known to cause any adverse effect. Rocuronium has an onset time similar to that of succinylcholine, no histamine release, and a prolonged duration of action. Either succinylcholine or rocuronium is acceptable for rapid sequence intubation (RSI) in acute asthma.

63.7. Which of the following is a risk factor for death in patients presenting with an asthma attack?  
A. Currently taking theophylline  
B. Family history of asthma  
C. Presence of symptoms for 1 week  
D. Recently ran out of inhaled corticosteroid (ICS)  
E. Use of three albuterol metered-dose inhalers (MDIs) per month  

**Answer:** E. The following are risk factors for death from asthma:  
- Past history of sudden severe exacerbations  
- Prior intubation for asthma  
- Prior asthma admission to an intensive care unit (ICU)  
- Two or more hospitalizations for asthma in the past year  
- Three or more emergency department (ED) care visits for asthma in the past year  
- Hospitalization or an ED care visit for asthma within the past month  
- Use of more than two MDI short-acting beta-2 agonist canisters per month  
- Current use of or recent withdrawal from systemic corticosteroids  
- Difficulty perceiving severity of airflow obstruction  
- Comorbidities such as cardiovascular diseases or other systemic problems  
- Serious psychiatric disease or psychosocial problems  
- Illicit drug use, especially inhaled cocaine and heroin

63.8. A 25-year-old woman presents with wheezing and shortness of breath from asthma. She was recently exposed to cigarette smoke. She denies cough and fever. You cannot get much more of a history from her at this time because she finds it difficult to speak in complete sentences. Her vital signs are: blood pressure, 136/85 mm Hg; heart rate, 110 beats per minute; respiratory rate, 32 breaths per minute; and temperature, 99°F (37.2°C). Her oxygen saturation is 92%. Her peak expiratory velocity-1 is 50% of predicted percentage. On physical examination, you note bilateral wheezing, regular tachycardia, and accessory muscle use. The remainder of her examination is normal. Over the course of 1 hour, she receives supplemental oxygen, three doses of nebulized albuterol (5 mg) mixed with ipratropium (0.5 mg), and oral prednisone 60 mg. She now reports feeling somewhat better. She speaks in longer sentences but still cannot speak in complete sentences. A repeat peak flow measurement is now 60% of predicted. Otherwise, there are no changes on a repeat physical examination. You plan to admit her to your ED observation unit. What is an appropriate next step in the management of this patient?  
A. Additional nebulized albuterol  
B. Intravenous (IV) magnesium sulfate  
C. IV methylprednisolone (Solu-Medrol)  
D. Oral montelukast  
E. Subcutaneous terbutaline  

**Answer:** A. This patient presents with a moderate-to-severe asthma exacerbation. She has responded to initial therapy but continues to have moderate symptoms. Additional adrenergic medications are indicated. Because she is tolerating nebulized medications and is responding, there is no need for IV or subcutaneous adrenergics, such as terbutaline. IV magnesium sulfate is a smooth muscle relaxant, but it is generally reserved for more severe asthma exacerbations. Oral and IV steroids have the same efficacy, and regardless of the route, only need to be administered every 6 to 8 hours. Montelukast is a leukotriene-modifying drug that is used in chronic management. Studies are ongoing with the use of these medications in acute exacerbations of asthma. They may improve pulmonary function tests (PFTs), but they do not change rates of admission or adverse outcomes.
Chronic Obstructive Pulmonary Disease

Ramin R. Tabatabai | Phillip F. Gruber

**PRINCIPLES**

**Background**

Chronic obstructive pulmonary disease (COPD) is one of the most common causes of death worldwide. Although prevalence estimates vary by measurement methods and by population studied, there is general agreement that COPD is underdiagnosed and under-reported. In patients older than 65 years old, the percentage of all hospitalizations related to COPD approaches 20%. COPD in the United States also accounts for a large financial burden, approximately 54 billion dollars annually, in large part due to hospitalizations and treatment of acute exacerbations. Cigarette smoking remains the most important cause for developing COPD, although other factors, such as genetic syndromes and noxious exposures, contribute significantly to the worldwide burden of COPD. Other important risk factors include occupational exposure, passive smoke inhalation, biomass heating fuels in poorly ventilated areas, and air pollution.

In response to the impact of COPD, large multinational collaborations, such as the Global Initiative for Chronic Obstructive Lung Disease (GOLD), sponsored jointly by the National Heart, Lung, and Blood Institutes and the World Health Organization (WHO), have developed guidelines and worldwide strategies to improve prevention and treatment of this debilitating lung disease. In their executive summary, the GOLD collaborators have updated their definition of COPD as “a preventable and treatable disease characterized by persistent airflow limitation that is usually progressive and associated with an enhanced chronic inflammatory response in the airways and the lungs to noxious particles or gas.” The definition specifically avoids mention of chronic bronchitis and emphysema, two entities that have been traditionally included in the definition of COPD.

Rather than using traditional definitions of COPD, the GOLD collaborators focus on airflow limitation as the principle feature of the disease. Airflow limitation is a direct result of a combination of parenchymal destruction and small airways disease. Both processes are a consequence of chronic inflammatory changes and present clinically in varying degrees amongst patients with COPD.

An exacerbation of COPD is characterized by worsening of the patient’s respiratory symptoms that is beyond normal day-to-day variations, requiring a change in medication. As the severity of the underlying disease progresses, so does the frequency of exacerbations. Moreover, in a subset of patients, incomplete recovery from acute exacerbations may reflect a contribution of exacerbations to the pathophysiology of disease progression.

**Pathophysiology**

Chronic airway inflammation is at the center of the pathophysiology for both COPD and asthma, but the inflammatory process differs in these two diseases. In asthma, the cellular response is largely eosinophil-mediated, whereas in COPD, neutrophils, CD8+ lymphocytes, and macrophages predominate in bronchial washings. Multiple inflammatory mediators are associated with lung parenchymal destruction in COPD, including tumor necrosis factor, leukotriene B4, and interleukin-8. These differences in the nature of the inflammatory response in COPD may account for its relatively poor response to anti-inflammatory treatment.

Progressive inflammation in COPD leads to airflow limitation and obstruction. However, not all patients who smoke or have exposure to noxious stimuli develop COPD, raising the possibility that other contributory factors such as genetics and environmental factors make some patients more susceptible to this disease.

In COPD, evidence of airway inflammation is found from the trachea down to the smallest peripheral airways. In the larger, more proximal airways, an increase in both the number and size of mucous-secreting goblet cells can result in the formation of mucous plugs, which further contributes to airflow obstruction. Damage to the endothelium impairs the mucociliary response that clears bacteria and mucous. Airway resistance and flow limitation are mainly due to damage to the distal, smaller airways where the diameter is 2 mm or less. Smaller airways are further compromised by damage to surrounding connective tissue, resulting in a loss of the radial support that normally maintains their patency during expiration.

Apart from the inflammatory changes that occur in the airways, COPD patients also experience damage to the lung parenchyma. Damage to these zones of air exchange ultimately results in the pathologic state known as emphysema. In cigarette smokers, the parenchymal damage will typically present in a centriacinar pattern, especially in the early stages of the disease. Emphysema is no longer routinely used in the definition of COPD, because it is a pathologic and anatomically defined condition. Chronic bronchitis on the other hand is a clinical condition defined by the presence of chronic productive cough for 3 months in each of 2 successive years, where other causes of chronic cough have been excluded. Most patients with COPD will have mixed features of both conditions.

There is compelling evidence that protease/anti-protease imbalance plays a role in the modification of the inflammatory cascade and resultant parenchymal destruction seen in COPD. Protease-mediated destruction of connective tissues, including elastin results in lung parenchymal damage and resultant emphysema. Anti-proteases protect against connective tissue destruction and are an integral component in the pathogenesis of patients with congenital α1-antitrypsin deficiency. Congenital α1-antitrypsin deficiency accounts for a small percentage of COPD patients and is recognized by the lack of the anti-protease enzyme that inhibits the protease enzyme, neutrophil elastase. The deficiency of this anti-protease results in uninhibited protease action, parenchymal destruction, and severe panacinar emphysema. Oxidative stress also plays a role in the inflammation associated with COPD. Oxidants are released after cigarette smoke and other noxious particles stimulate inflammatory cells, such as neutrophils and macrophages. The end result of this oxidative and inflammatory stress is airflow limitation from both parenchymal destruction and airway narrowing.

The combination of airway obstruction, parenchymal destruction, and obliteration of the pulmonary vascular bed results in failure of gas exchange. Blood gas analysis may reveal both hypoxemia and hypercapnia. As the overall size of the pulmonary
vascular bed decreases with time, chronic hypoxia induces a thickening of the vessel walls, which contributes to the development of pulmonary hypertension, polycythemia and, eventually, right-sided heart failure (cor pulmonale).

Although the precise mechanisms are ill-defined, the pathologic processes of COPD extend beyond the cardiac and pulmonary systems. The effects of circulating inflammatory mediators, oxidative stress, and protease/anti-protease imbalance may be responsible for the non-pulmonary complaints of weight loss, muscular wasting, metabolic derangements, and depression often seen in the later stages of disease. COPD influences a variety of management decisions in the emergency department (ED), ranging from the choice of agents for procedural sedation and rapid sequence intubation to the appropriate disposition of patients with non-pulmonary diagnoses.

**CLINICAL FEATURES**

**Symptoms and Natural History**

A clinical diagnosis of COPD should be considered in any patient with dyspnea, chronic cough or sputum production, and a history of risk factors for the disease. COPD patients have a long premorbid course during which decreases in airflow indices can be measured in the absence of significant symptoms. Airflow limitation can be measured via spirometry in the outpatient setting, which may be the earliest indicator and best predictor of early onset COPD. Intermittent cough or shortness of breath on exertion may be easily misattributed to poor physical conditioning. Moreover, patients may remain asymptomatic for many years by gradually limiting their activities in proportion to their pulmonary reserve. After several years, a daily productive cough frequently develops, and periods of dyspnea, the cardinal symptom of airflow limitation, increase. Note that the absence of wheezing does not exclude the diagnosis of COPD; nor does the presence of wheezing confirm the diagnosis. The clinical progression of COPD is slow and insidious, with gradual decreases in airflow punctuated by increasingly frequent and debilitating exacerbations. Eventually the patient becomes truly incapacitated by dyspnea on minimal or no exertion. Profound muscle wasting and weight loss and the emergence of cor pulmonale or chronic ventilatory failure are characteristic of end-stage disease. Figure 64.1 depicts the progression of COPD over time.

### Severity of Airflow Limitation

Indicative of persistent airflow limitation, a forced expiratory volume in 1 second (FEV1)/forced vital capacity (FVC) less than 0.70, measured by spirometry, is now required to make the diagnosis of COPD. Although spirometry is important for outpatient evaluation of COPD, there is currently no role for spirometry in the ED. Once the diagnosis is made, the GOLD collaborators define four grades based on the patient’s FEV1. The grades are divided beginning with a GOLD I grade (mild COPD) where spirometry is abnormal but symptoms may not yet be apparent, and ending in GOLD IV grade (very severe COPD), when FEV1 is less than 30% of predicted (Table 64.1). These grades can be predictive of an increased frequency of exacerbations as well as an increased risk of death.79 Despite the GOLD classification of airflow limitation, the best predictor of exacerbations continues to be a history of previous exacerbations.80

**Physical Examination**

The division of patients with COPD into two phenotypes, the “blue bloater” (for the patient with chronic obstructive bronchitis) and the “pink puffer” (for the patient with emphysema), is outdated because many patients with COPD do not conform to these descriptions. Nonetheless, these classic images do highlight some of the important clinical features that may be encountered in the patient with COPD and have implications for management. Most patients have some combination of chronic obstructive bronchitis and emphysema and appear with a mixture of the syndromes described later. The precise identification of which process is predominant is less important than the evaluation of each patient and formulation of a specific treatment plan. In particular, the degree of chronic hypoxemia and dependence on home oxygen therapy, the presence of cor pulmonale, and evidence of comorbid illness (such as, ischemic heart disease) should be determined.

In patients in whom chronic bronchitis predominates, the findings are those of chronic respiratory failure and cor pulmonale. Little air hunger or anxiety is present, and the combination of polycythemia and hypoxemia creates a plethoric, cyanotic appearance. Cough, as the clinical hallmark of bronchitis, is prominent and, when vigorous, causes expectoration. If acute ventilatory failure is present, the patient’s consciousness is clouded. This often is described as “irritable somnolence,” and asterixis may

COPD, Chronic obstructive pulmonary disease; FEV1, forced expiratory volume in 1 second; FVC, forced vital capacity; GOLD, Global Initiative for Chronic Obstructive Lung Disease.

be present. Chronic ventilatory failure and cor pulmonale lead to prominent peripheral edema and jugular venous distention. If there is relatively little emphysema, the thoracic anteroposterior diameter is normal, and the diaphragm is not abnormally low. The presence of severe bronchopulmonary secretions is evidenced by scattered rhonchi and rales, especially at both lung bases posterolaterally. These patients often have chronic carbon dioxide retention, requiring close monitoring of oxygen therapy because of their relative dependency on hypoxic drive for ventilation.

When emphysema predominates, the patient is often thin, anxious, alert and oriented, dyspneic, and tachypneic and uses accessory muscles of breathing. The patient often self-administers positive end-expiratory pressure (PEEP) by using a pursed lip exhalation pattern to increase intraluminal bronchial pressure and provide internal support for bronchial walls that have lost their external support. Such patients usually assume a sedentary existence, chronically hunched forward. Gross lung over-inflation occurs, with a low immobile diaphragm and an increased anteroposterior diameter of the thorax. Percussion of the chest reveals hyper-resonance, and auscultation demonstrates diminished breath sounds with faint end-expiratory rhonchi. Despite air hunger caused by the extensive lung parenchyma destruction, the patient maintains adequate oxygen saturation and often has normo- or hypercapnia. The heart is small and hypodynamic, and the blood pressure is usually low.

**DIFFERENTIAL DIAGNOSES**

The differential diagnosis of the acutely dyspneic and hypoxic patient is broad. The condition that is most commonly mistaken for COPD is cardiogenic pulmonary edema, which may manifest with dyspnea and wheezing ("cardiac asthma"). Other serious cardiac causes include myocardial ischemia and pericardial effusion. Important pulmonary diagnoses include pneumothorax, pulmonary embolism (PE), pneumonia, asthma, acute respiratory distress syndrome, bronchiectasis, pulmonary fibrosis, pleural effusions, and tuberculosis. In addition, metabolic acidosis and dyspnea may manifest as dyspnea and ventilatory failure.

In most cases, a COPD exacerbation can be differentiated from acute congestive heart failure (CHF) on clinical grounds. Nonetheless, a significant percentage of patients who come to the ED with acute dyspnea and an established diagnosis of COPD are ultimately diagnosed with acute CHF despite having no prior history of heart failure. The addition of a B-type natriuretic peptide (BNP) assay to the ED evaluation of such patients identifies some in whom a new diagnosis of CHF is not suspected. Because BNP can be elevated in association with right ventricular stretch, incautious interpretation of an elevated BNP may lead the emergency clinician to favor the diagnosis of acute left-sided CHF and overlook cor pulmonale and PE, both critical considerations in the patient with COPD. Moreover, acute CHF and COPD often coexist, and even severe elevations in BNP do not obviate the identification and treatment of acute pulmonary pathology. Thus, although BNP measurement may be helpful in the evaluation of the acutely dyspneic patient, it cannot be interpreted in isolation and must not supplant clinical judgment.

Acute pneumothorax can occur with COPD secondary to ruptured bullae. This diagnosis should be actively pursued in patients with worsening respiratory status, especially when its onset is abrupt. In older patients with COPD, chest pain is often absent. A small pneumothorax cannot be excluded by physical examination and can be very difficult to detect on inspiratory chest films, especially in patients with bullous emphysema. Bedside ultrasound is a useful modality for diagnosing pneumothorax in the ED. In assessing for pneumothorax, however, the presence of COPD may result in false-positive results. Ultimately, a chest computed tomography (CT) should be performed when clinical suspicion of a pneumothorax is high and plain films and ultrasound are nondiagnostic.

Patients with COPD are often sedentary and may consequently be at increased risk for venous thromboembolic disease. The patient with cor pulmonale is at even higher risk because of increased blood viscosity, high peripheral venous pressure, and venous stasis. PE should be considered when an acute exacerbation is more severe than prior episodes, particularly if deterioration occurs quickly with no other apparent cause.

Unfortunately, because there is significant overlap in presentation, differentiating PE from a COPD exacerbation can be extremely difficult, and PE should remain in the differential diagnosis especially when the patient does not respond to standard treatments.

Lobar atelectasis occurs as a result of mucous plugging of bronchi and can be lethal. Similar to pneumothorax and PE, it may manifest abruptly. The chest film may show linear horizontal streaking or small flare-like shadows; more often, it is normal. Hypoxic reactive airway patients with a protracted course unresponsive to bronchodilators should be presumed to have either PE or atelectasis. If PE is excluded, such patients often require endotracheal intubation and aggressive interventional pulmonary toilet.

Pneumonia is a common, devastating complication of COPD that leads to mortality. In COPD patients, older age, higher COPD severity, comorbidities, and previous episodes of pneumonia are risk factors for pneumonia. Classic symptoms of cough, fever, and toxicity are seen less often than the more nonspecific and subtle symptoms of malaise, weakness, decreased activity, and anorexia. Leukocytosis may or may not be present, and its presence is not necessarily indicative of infection because of its low specificity. Radiographic infiltrates may be subtle or absent, especially in patients whose lung parenchyma has been distorted or obliterated by emphysema, and comparison to previous radiographic studies may be necessary. Patients with radiographic signs of pneumonia have a higher mortality and hospital length of stay when compared to those without radiographic findings.

Rib fractures occur in patients with COPD secondary to trauma, but in patients receiving steroids, they can be caused by vigorous cough alone. COPD has also been shown to have an association with osteoporosis, putting them at even higher risk of fractures. When rib fractures are identified, secondary pulmonary contusion and pneumothorax also should be considered.

Lung malignancy is always a consideration in COPD, because these patients have a twofold to fivefold increase in lung cancer risk even when compared to other smokers without COPD. Patients presenting with COPD and radiographic abnormalities should have these findings noted in the chart and follow-up arranged.

There are other treatable chronic, nonobstructive pulmonary diseases. For example, bronchiectasis is an often overlooked cause of purulent expectoration. It may accompany and contribute to COPD exacerbations. Although its pathologic characteristic is dilation, not constriction, of airways, the secretions that accompany it may result in an obstructive component. Active tuberculosis is considered in patients with infiltrates (not only apical), a chronic wasting course, and risk factors for active disease, such as human immunodeficiency virus (HIV) disease and homelessness. Sarcoïdosis, which can manifest with chronic cough and constitutional symptoms, usually causes a dry cough and may be suggested on the basis of the radiographic appearance.

Finally, there are some iatrogenic causes of acute decompensation in COPD. Many agents, such as beta-blockers and cholinergic agents, may directly or indirectly produce bronchospasm. A second group of potentially deleterious drugs is sedatives. It is important not to confuse hypoxic agitation with anxiety because patients with chronic respiratory failure are abnormally
BOX 64.1  
Causes of Acute Decompensation in the Patient With Chronic Obstructive Pulmonary Disease

ACUTE EXACERBATIONS  
Infectious  
Viral  
- Rhinovirus, respiratory syncytial virus, coronavirus, influenza virus  
Bacterial  
- Haemophilus influenzae, Streptococcus pneumoniae, Moraxella (Branhamella) catarrhalis, Pseudomonas aeruginosa  
Atypical bacteria  
- Chlamydia pneumoniae, Legionella  

Air Pollution  
- Nitrogen dioxide  
- Ozone  
- Particulates, dust

OTHER CRITICAL EVENTS  
- Pneumothorax  
- Pulmonary embolism (PE)  
- Lobar atelectasis  
- Congestive heart failure (CHF)  
- Pneumonia  
- Pulmonary compression (eg, obesity, ascites, gastric distention, pleural effusion)  
- Trauma (eg, rib fractures, pulmonary contusion)  
- Neuromuscular and metabolic disorders  
- Unrelated treatable chronic pulmonary disease (bronchiectasis, tuberculosis, sarcoidosis)  
- Noncompliance with prescribed treatment regimens  
- Iatrogenic  
  - Inadequate therapy  
  - Inappropriate therapy (eg, deleterious drugs)

sensitive to the respiratory depressant effect of sedatives, and even small doses may significantly worsen hypoventilation. Box 64.1 summarizes the causes of acute decompensation in the patient with COPD.

DIAGNOSTIC TESTING

Currently, the diagnosis of an acute COPD exacerbation is clinical and based on an increase in dyspnea, cough, or sputum production that is beyond normal day-to-day variation. Other diagnostic modalities can help guide management but should not be a substitute for the patient’s clinical presentation.

Pulse Oximetry, Blood Gas Analysis, and Capnography

Pulse oximetry is a core element of the evaluation and monitoring of the acutely exacerbated COPD patient. Comparison with prior values, both in crisis and in baseline state, helps to interpret measurements obtained during an acute exacerbation. The change in pulse oximetry from baseline or in response to emergency therapy is generally more important than absolute levels.

The stages of COPD severity correlate with arterial gas tensions. Abnormal ventilation-perfusion relationships of COPD produce only modest decreases in arterial partial pressure of oxygen (PaO₂) in its early stages (80 to 100 mm Hg). Later in the course of the disease, hypoxemia below 60 mm Hg stimulates respiratory centers, producing hyperventilation (partial pressure of carbon dioxide [PCO₂] over 35) and acute respiratory alkalosis.

As pulmonary dysfunction progresses, the work of hyperventilation becomes cost-ineffective—that is, more carbon dioxide is produced by the effort than is cleared by the increased ventilation. Eventually, alveolar hypoventilation impairs gas exchange, leading to carbon dioxide retention and acute respiratory acidosis. With renal compensation through bicarbonate retention, the pH normalizes. Finally, when acute ventilatory failure is superimposed at this late stage of the disease, an elevated PCO₂ lowers pH, and elevated bicarbonate are found.

Although measurement of ABGs was once a mainstay of ED evaluation of COPD patients, we do not recommend their routine use. Response to therapy can often be monitored sufficiently by the patient’s clinical status and noninvasively by capnography and pulse oximetry. The decision to intubate a patient or initiate bi-level positive airway pressure (BiPAP) should be guided by the overall state of the patient, progression of fatigue, comorbid illness, and response to therapy. Patients with very poor blood gas values may do well without intubation or BiPAP, whereas others with mildly disturbed values may require urgent airway intervention.

If an ABG is performed, the presence of respiratory failure that is unresponsive to therapy (defined as PaO₂ < 60 mm Hg with or without a PaCO₂ > 50 mm Hg, and pH < 7.25 mm Hg) warrants consideration of admission to an intensive care unit, but clinical evaluation is much more important than any particular blood gas values. The GOLD guidelines recommend obtaining ABGs prior to intubating a COPD patient. Although it may be useful for post intubation management to know the patient’s serum pH, the authors do not support any delay in care for obtaining a blood gas.

The correlation of venous blood gases (VVGs) and ABGs has been studied in both COPD patients and in patients receiving noninvasive mechanical ventilation. They yield similar results with regard to serum pH and bicarbonate levels, whereas PCO₂ levels demonstrate less agreement. 20,21

Waveform capnography, which represents the continuous quantitative measurement of exhaled carbon dioxide, has emerged as a useful monitoring tool in patients with respiratory distress or undergoing procedural sedation. Unfortunately, in patients with COPD, the actual end-tidal carbon dioxide (ETCO₂) measurement obtained from capnography does not correlate well with the arterial PCO₂ especially in more severe disease. Therefore, capnography and ETCO₂ measurement should not be considered as a part of the decision-making process to predict PaCO₂ level in COPD patients. 22

Chest Radiography

In patients who are known to have COPD, the primary role of the chest radiograph is to evaluate for the presence of other alternative diagnoses. A chest x-ray can determine whether there is an acute, treatable cause for clinical deterioration, especially pneumothorax or parenchymal consolidation (atelectasis secondary to mucous plugging, pneumonia, or obstruction by tumor). Otherwise, the chest radiograph is of limited use and may exhibit a range of chronic changes, depending on disease severity and the relative degree of the various pathologic processes. Findings may include hyperinflated lung fields, decreased vascular markings, and a small cardiac silhouette or, in contrast, normal inflation with increased vascular markings and an enlarged heart. 23 In cor pulmonale, impingement on the retrosternal airspace by the enlarged right ventricle can be seen on the lateral film.

Bullae may also be present and may mimic or mask a pneumothorax. In addition, chest radiography may reveal important coexistent pathology, including CHF, effusions, and tumors. Routine chest radiography is recommended for evaluation of the patient with an acute COPD exacerbation.
Spirometry

Although spirometry plays a key role in making a diagnosis of COPD in the outpatient setting, there is no role for pulmonary function testing in the ED because it is difficult to perform and inaccurate in patients with acute exacerbations. Measurement of forced expiratory volume is simple to perform but is less useful in COPD than in asthma, where airway obstruction is more acutely reversible.

Sputum Examination

Although a clinical history of changes in sputum production and purulence can support a diagnosis of COPD exacerbation, diagnostic testing of sputum does not provide clinical value in the ED setting.

As with asthma, viral infection appears to be a frequent inciting agent in COPD exacerbations. Commonly implicated viruses include rhinovirus, respiratory syncytial virus, coronavirus, and influenza viruses. Although rapid influenza tests during epidemics may prompt antiviral therapy in patients with severe COPD, other viral tests are not useful.

Controversy remains regarding the role of bacterial pathogens in acute exacerbations of COPD. Almost half of all exacerbations are associated with negative cultures for the typical respiratory pathogens, such as Haemophilus influenzae, Streptococcus pneumoniae, Moraxella (Branhamella) catarrhalis, and Pseudomonas aeruginosa. In addition, these organisms are recovered from the tracheobronchial tree of patients in their chronic, steady state, suggesting that bacteria may play a more important role in the pathogenesis of chronic COPD than in acute exacerbations.

Electrocardiogram and Cardiac Monitoring

The classic descriptions of P pulmonale (peaked P waves in leads V2, V3, and aVF), low QRS voltage, clockwise rotation, and poor R wave progression in the precordial leads are interesting correlates of COPD but are both insensitive and nonspecific. The presence of electrocardiogram (ECG) criteria for right ventricular hypertrophy (RVH) suggests established cor pulmonale. These findings, however, can be easily obscured on the ECG by other processes, and the absence of criteria for RVH cannot be relied on to rule out cor pulmonale.

In severely ill patients or those with concomitant chest pain, continuous ECG monitoring may be helpful, at least for the initial phase of the patient’s evaluation and treatment. ECG monitoring can detect dysrhythmias associated with COPD exacerbations and changes of rate and rhythm in response to therapy. The most common dysrhythmias associated with COPD are atrial tachydysrhythmias, such as atrial fibrillation and multifocal atrial tachycardia. Although atrial fibrillation may require treatment with rate control or conversion, multifocal atrial tachycardia often resolves with the treatment of the COPD exacerbation itself.

Blood Tests

Routine hematologic evaluation adds little to the treatment of the patient with COPD and acute exacerbation. A complete blood count (CBC) may reveal polycythemia associated with chronic hypoxia. An elevated white blood cell (WBC) count is nonspecific and should not be interpreted as indicative of coexistent infection, nor should a normal-range WBC count support a contention that infection is not present. Therefore, obtaining a CBC is not recommended for an acute exacerbation responsive to initial therapy.

The measurement of BNP, released by myocardial tissue in response to stretch and a critical part of volume homeostasis, may be useful as a diagnostic adjunct in patients with acute dyspnea. BNP values above 500 pg/mL are suggestive of decompensated heart failure, and levels below 100 pg/mL are very suggestive of the absence of CHF.25,26

Despite the sensitivity of BNP in detecting the physiologic presence of heart failure, its utility as a routine test in the assessment of dyspneic patients is debated. Additionally, the interpretation of a BNP is of limited value in certain patient populations. For example, we do not recommend routine BNP studies in patient with renal failure on hemodialysis, because these numbers are often elevated regardless of whether the patient has heart failure.27 We do recommend BNP testing in the patient who has both COPD and CHF who presents with dyspnea to help discern whether the patient is primarily presenting with a CHF exacerbation or a COPD exacerbation. Although we do not recommend the routine use of BNP in all acutely dyspneic patients in the ED, a BNP may be useful in the appropriate clinical setting in assessing for CHF versus COPD in the undifferentiated patient with dyspnea and/or wheezing.

Troponins are often ordered in the ED evaluation of the acutely dyspneic patient. In the presence of an abnormal ECG or when the patient’s dyspnea is more severe than expected, we do recommend ordering a troponin in the acute exacerbation COPD patient. Although they rarely identify acute cardiac pathology missed by ECG, elevated troponins in patients with COPD exacerbation are associated with increased in-hospital and 30-day mortality, and should be considered in the decision to admit.

MANAGEMENT

The three classes of medications most often used in the management of acute COPD exacerbations are short-acting bronchodilators, steroids, and antibiotics, and each will be reviewed in further detail. An overview of the emergency assessment and management of COPD exacerbations is provided in Table 64.2.

OxygeNation and Ventilation

All COPD patients in acute respiratory distress require continuous ECG and pulse oximetry monitoring. Patients who are hypoxemic should receive controlled oxygen therapy, with a goal

**Proposed Indications for Mechanical Ventilation**

Respiratory arrest
Worsening level of consciousness despite maximal therapy*
Cardiovascular instability (shock, heart failure)*
NIPPV failure or exclusion criteria (see Table 64.3)
Severe dyspnea with use of accessory muscles and paradoxical abdominal motion*
Severe tachypnea*
Life-threatening hypoxia
Severe acidosis and hypercapnia*
Other complications (metabolic abnormalities, sepsis, pneumonia, pulmonary embolism [PE], barotraumas, massive pleural effusion)*

*For several of these parameters, criteria are deliberately imprecise; clinical decisions must be individualized in each case.

**General Drug Therapy**

**Bronchodilators**

Although bronchospasm is not the primary inciting event in acute COPD exacerbation, both short-acting beta-agonists and anticholinergic agents are considered first-line agents. The choice of agent for treating a given patient may depend on the respective side effect profiles of these two classes of drugs, although the combination of both medications is safe in most patients.

Although many choices are available, inhaled albuterol, which is short acting with selective beta-2 receptor action, is the beta-agonist of choice. The nebulization dose of albuterol is 2.5 to 5.0 mg (0.5 to 1.0 mL of 0.5% solution). Most patients tolerate two to three rapid successive doses of oxygen-nebulized beta-agonist with little difficulty. Therapy must occasionally be titrated if the side effects of tremor, tachycardia, or ventricular ectopy are significant.

Anticholinergic agents block muscarinic receptors and prevent smooth muscle contraction while decreasing the release of secretions from submucosal glands. Inhaled anticholinergic agents are as effective as beta-2 agonists in COPD and can be used alone or in conjunction with beta-2 agonists as first-line therapy in acute exacerbations. Although evidence regarding the efficacy of their coadministration is controversial, for moderate to severe exacerbations in the ED, these drugs should be given together for their possible synergistic effects. Anticholinergics can be administered by nebulization or metered-dose inhaler (MDI) and are also effective for intubated patients. Ipratropium bromide, a quaternary ammonium compound, has been extensively studied in COPD. The nebulization dose is 0.5 mg, which may be repeated every half hour for a total of three doses and subsequently every 4 hours. Although anticholinergics have powerful bronchodilating properties, caution should be exercised in patients with preexisting arrhythmias and cardiac disease, because these medications may put the patient at higher risk of adverse cardiac events.

Long-acting bronchodilator agents, such as salmeterol (beta-2 agonist) and tiotropium (anticholinergic), are used for chronic stable COPD. Although these agents may reduce the frequency of COPD exacerbations, they have no role in ED management of acute exacerbation.

The COPD patient with a mild to moderate exacerbation may be able to self-administer bronchodilator agents through use of an MDI with a spacer device, which is as effective as nebulized treatment. Studies also demonstrate the efficacy and cost benefit of MDI therapy over nebulization in acutely hospitalized patients. Because of the smaller dose delivered with single MDI puffs, MDI protocols often involve multiple puffs at each administration interval. This mode of therapy should only be considered for stable, cooperative patients. The intubated patient should receive bronchodilator therapy via inline nebulization.

Methylxanthines, principally aminophylline, were once commonly used in COPD exacerbations. Evidence is not supportive of their use, however, because they do not improve outcomes, even when combined with beta-agonists and anticholinergic agents. Recommendations that include methylxanthines as a second-line therapy when other modalities have failed are tempered by concerns about toxicity, which may outweigh the positive effects of these agents. If a rare patient is encountered who is taking methylxanthines on a chronic, ambulatory basis, additional methylxanthines should not be used in the course of treatment in the ED.

In addition to beta agonists and anticholinergics, magnesium sulfate may also demonstrate a bronchodilatory effect that is thought to occur through bronchial smooth muscle relaxation. Current guidelines make no recommendations for the use of magnesium in acute exacerbation COPD. Although there is some evidence that IV magnesium sulfate may play a role in potentiating the bronchodilatory effects of beta-agonists, there is currently insufficient high quality evidence to recommend routine administration of IV or inhaled magnesium in the treatment of COPD in the ED.

**Corticosteroids**

The anti-inflammatory effects of steroids provide a strong rationale for their use in acutely ill patients with COPD. Although steroids may not alter the immediate ED course, their use does result in a modest decrease in the relapse rate of acute exacerbations and improvement of dyspnea. When initiating steroid therapy in the acute exacerbation COPD patient, the emergency clinician must decide on the optimal dose and route of administration. Recommended doses and routes of corticosteroids have varied widely in published studies. There is some evidence that shorter courses of systemic steroids (less than 7 days) are likely to be as effective as longer 10 to 14 day courses.

Regarding the route of administration, guidelines continue to recommend oral systemic corticosteroids over IV corticosteroids because they generally provide similar efficacy but have the advantage of reduced cost and higher ease of administration. Current evidence supports the use of oral prednisone for both admitted and discharged patients though less evidence exists for the critically ill COPD patient admitted to the ICU. Systemic IV glucocorticoids should be administered to patients who are unable to tolerate oral steroids due to severity of illness or other causes of per os (by mouth; PO) intolerance. For COPD exacerbation patients, prednisone 40 mg PO or methylprednisolone 1 to 2 mg/kg intravenous (IV) are acceptable initial steroid doses. We recommend use of lowest effective dose and shortest effective duration of therapy to minimize common adverse effects, such as hyperglycemia, myopathy, and immunosuppression.

**Antibiotics**

In contrast to asthma exacerbation and acute bronchitis in the setting of normal lung function, in which antibiotics are of no benefit, some COPD patients with an acute exacerbation appear to benefit from antibiotic therapy. Despite a large body of literature on the topic, the exact role of antibiotics in COPD continues to remain controversial. The GOLD collaborators recommend administering antibiotics to patients with an increase in sputum purulence and either increased dyspnea or increased...
antagonists, progesterone, acetazolamide, doxapram, and almitrine have been studied in patients with COPD, including opioid trine. Doxapram appears to be the most effective of these agents controversial. Antibiotics in this patient population remains inconsistent and clinically but without any definitive mortality benefit. For discharged admitted patients, patients receiving antibiotics improved clinically with antibiotics that reflect local patterns of antibiotic sensitivity to S. pneumoniae, H. influenzae, and M. catarrhalis. Currently, antibiotic therapy in COPD patients typically involves the use of aminopenicillins with or without clavulanic acid, macrolides, or tetracyclines. Patients with frequent exacerbations, severe airflow limitation, or mechanical ventilation may have pseudomonal involvement or other resistance patterns requiring expanded spectrum antibiotics, such as fluoroquinolones. Although antibiotics with broader-spectrum coverage, such as the fluoroquinolones and third-generation cephalosporins, are commonly prescribed, the evidence for the superiority of these newer agents is indirect. Studies suggest that short (3- to 5-day) courses of antibiotics, such as respiratory fluoroquinolones or macrolides, may be as effective as more traditional, longer (7- to 14-day) courses of beta-lactams and tetracyclines. There is limited data, however, on the optimal antibiotic regimen in these patients. The authors recommend prescribing a short course of macrolides or a standard course of tetracycline for uncomplicated outpatient and inpatient COPD exacerbations requiring antibiotics. For more complicated inpatient COPD admissions, consideration of fluoroquinolones or extended spectrum beta-lactams is appropriate in patients at risk for antibiotic resistance, such as mechanical ventilation or those with multiple and frequent hospitalizations.

Based on the GOLD recommendations and Cochrane review findings, the authors recommend antibiotic administration to all patients admitted for acute exacerbation COPD. Because the literature is less clear on routine antibiotic administration for discharged patients, the emergency clinician can use his or her clinical judgment in deciding to prescribe antibiotics. In general, the emergency clinician should be more likely to consider antibiotics if the patient has an increase in sputum purulence and either increased dyspnea or increased sputum volume.

Other Mucokinetic Medications and Mucus Clearance Strategies. Mucus production and cough are cardinal symptoms of COPD. Unfortunately, little evidence exists that mucokinetic agents are successful, and they are not recommended. Nebulized saline, oral expectorants, and chest physiotherapy also fail to demonstrate benefit.

Heliox. Helium-oxygen mixtures decrease the work of breathing and improve airflow by virtue of their low density. Such mixtures, however, fail to demonstrate clinical benefit in patients with COPD exacerbations.

Respiratory Stimulants. Several respiratory stimulants have been studied in patients with COPD, including opioid antagonists, progesterone, acetazolamide, doxapram, and almitrine. Doxapram appears to be the most effective of these agents and works by stimulating chemoreceptors in the carotid bodies, stimulating the brainstem respiratory center. Although doxapram can effect small, temporary improvements in blood gas exchange in the first hours of treatment, it is less effective than other techniques, such as BiPAP. Respiratory stimulants are therefore not recommended for routine use in the ED.

Prevention of Chronic Obstructive Pulmonary Disease Exacerbations via Anti-Inflammatory Therapy. Preliminary evidence points to the possibility that other therapeutic strategies may reduce exacerbation frequency via immunomodulatory effects. Roflumilast, a selective phosphodiesterase 4 inhibitor, may be of benefit in the outpatient setting in the prevention of COPD exacerbations. However, there does not appear to be any current role for the ED use of roflumilast in the management of acute exacerbations.

Macrolide antibiotics, such as erythromycin and azithromycin, also exhibit immunomodulatory and anti-inflammatory properties in addition to their antibiotic effects and have therefore also been suggested in the prevention of COPD exacerbation. Although studies have shown some promise in reduction of exacerbations, GOLD does not currently recommend the use of daily macrolides for this purpose given its potential to increase antibiotic resistance and QT intervals, resulting in cardiac toxicity.

Future Therapies for Chronic Obstructive Pulmonary Disease Exacerbations. Bedoradrine is a highly selective beta-adrenergic agent for management of exacerbations. A phase II study in patients with an exacerbation, this agent was given by slow IV injection and resulted in prolonged bronchodilation without an increase in adrenergic adverse events. We do not currently recommend the use of this medication until further studies are completed.

In summary, current ED management of COPD exacerbations involves supplemental oxygen to prevent severe hypoxia and noninvasive or invasive ventilatory support when necessary. Every patient should receive short-acting bronchodilator therapy and oral systemic steroids. Finally, supplemental antibiotics should be considered depending on the individual patient presentation.

DISPOSITION

Significant deterioration from baseline is the general guideline for admission of patients with COPD. Important factors in the decision include the presence of coexisting conditions, failed outpatient management for the current exacerbation, and lack of improvement while in the ED. The GOLD collaborators propose guidelines for admission, and these are adapted in Box 64.3. If the

**BOX 64.3**

General Guidelines for Admission of the Patient With Chronic Obstructive Pulmonary Disease

- Significant worsening of symptoms from baseline
- Inadequate response of symptoms to emergency department (ED) management
- Significant comorbid condition (eg, pneumonia, heart failure)
- Worsening hypoxia or hypercarbia (from baseline)
- Inability to cope at home or insufficient home resources

When a decision is made to discharge the patient, attention should also be directed to the patient’s vaccination status, proper technique of inhaler use, evaluation of outpatient support systems, appropriate referrals, and, perhaps most important, smoking cessation.

### KEY CONCEPTS

- **Acute exacerbation of chronic obstructive pulmonary disease (COPD)** is defined by a worsening of the patient’s respiratory symptoms that is beyond normal day-to-day variations, requiring a change in medication.
- Cigarette smoking remains the most important single cause for developing COPD. However, genetic syndromes, occupational exposures, passive smoke inhalation, biomass heating fuels in poorly ventilated areas, and air pollution are also important contributory risk factors worldwide.
- Consider other life-threatening diagnoses in the acute exacerbation COPD patient who does not respond to standard treatments. Such diagnoses include acute heart failure, pulmonary embolism (PE), pneumonia, mucous plugs, and pneumothorax. Emergency clinicians should maintain a high index of suspicion for lung malignancy in COPD patients.
- The most common dysrhythmias associated with COPD are atrial fibrillation and multifocal atrial tachycardia. Classic electrocardiogram (ECG) findings for COPD include P pulmonale, low QRS voltage, and poor R wave progression but none of these findings are sufficiently sensitive or specific for COPD and should not be relied upon to make the diagnosis.
- Noninvasive ventilator support/bi-level positive airway pressure (BiPAP) is an accepted and effective alternative to invasive ventilation in COPD patients with moderate to severe COPD exacerbation. However, BiPAP cannot substitute for invasive ventilation in patients who are hemodynamically unstable, markedly agitated, and uncooperative or in whom respiratory arrest appears inevitable.
- The most important factor in the decision to intubate is the patient’s clinical status, not arterial blood gas (ABG) measurements. Even in the face of a significant rise in partial pressure of carbon dioxide (PCO₂) with oxygen administration, intubation may be unnecessary if the patient’s clinical status has stabilized.
- The three classes of medications most often used in the management of acute COPD exacerbations are bronchodilators, steroids, and antibiotics.
- Bronchodilators, such as albuterol (short-acting beta-2 receptor agonist) and ipratropium bromide (anticholinergic), are considered first-line agents in the treatment of acute exacerbation COPD and may provide a synergistic treatment effect.
- Acute exacerbation COPD patients should receive systemic corticosteroids. Oral and intravenous (IV) forms demonstrate similar efficacy, but patients who are unable to tolerate the oral form due to respiratory failure or per os (by mouth; PO) intolerance should receive the IV form.
- Antibiotics should be administered to all acute exacerbation COPD patients requiring both intensive care unit (ICU) and non-ICU admission. In discharged patients, the emergency clinician should consider antibiotics if the patient has an increase in sputum purulence and either increased dyspnea or increased sputum volume.
- Although there is some evidence that IV magnesium sulfate may play a role in potentiating the bronchodilatory effects of beta-agonists, there is currently insufficient high quality evidence to recommend routine administration of IV or inhaled magnesium in the treatment of COPD in the emergency department (ED).
- Currently there is no role for methylxanthines, heliox, or respiratory stimulants in the management of COPD patients in the ED.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
REFERENCES
Answer: E. Most smokers do not get airflow limitations. Genetic and environmental factors play important roles. The destructive inflammatory process, once initiated, continues to some degree despite smoking cessation. This cascade, as compared with asthma, involves neutrophils rather than eosinophils, different leukotrienes, and tumor necrosis factor expression. Progression cannot be precisely predicted.

64.2. Frequent chronic obstructive pulmonary disease (COPD) exacerbations can be anticipated when a patient’s baseline forced expiratory volume in one second (FEV₁) falls below which of the following?
A. 75%
B. 50%
C. 25%
D. 10%
E. There is no correlation.

Answer: B. This corresponds to stage 3/stage 4 COPD.

64.3. What is the most frequent etiology for chronic obstructive pulmonary disease (COPD) exacerbation?
A. Bacterial
B. Environmental
C. Idiopathic
D. Viral
E. Other systemic illnesses

Answer: D. Idiopathic accounts for approximately 30%. The role of bacterial pathogens is unclear, with chronic colonization suggesting a greater role in the chronic progression rather than acute flares. Environmental causes play a role, but this is difficult to define.

64.4. A 69-year-old man with known chronic obstructive pulmonary disease (COPD) presents with an acute 2-day flare of his disease. Current medications are albuterol inhaler, amiodipine 10 mg/day for hypertension, and furosemide 40 mg/day. His primary symptoms are exertional dyspnea and cough with a change to yellow sputum production from clear. Vital signs are: blood pressure, 160/100 mm Hg; respiratory rate, 24 breaths per minute; heart rate, 120 beats per minute; oral temperature, 98.4°F (36.9°C); and oxygen saturation, 91%. Chest radiograph shows hyperinflation with no infiltrate. Electrocardiography (ECG) shows multifocal atrial tachycardia (MAT). Which of the following is true?
A. As for acute bronchitis, antibiotics are of no benefit for acute COPD exacerbation.
B. Beta-agonist and corticosteroid treatment mirror recommendations for acute asthma flares.
C. If endotracheal intubation is required, ventilatory settings to maintain a partial pressure of oxygen (Pao₂) greater than 60 mm Hg and a partial pressure of carbon dioxide (Paco₂) 40 mm Hg or less are recommended.
D. Outpatient management is indicated.
E. Pharmacologic intervention should be initiated early for rate control of MAT.

Answer: B. The dosing of beta-agonists and corticosteroids is very similar to guidelines for asthma. Unlike acute bronchitis, COPD patients who have experienced a change in sputum production often benefit from empirical antibiotics. MAT does not typically require treatment and often resolves as the COPD flare is ameliorated. Mechanical ventilation of COPD patients is aimed acutely at maximizing oxygenation, with as low a forced inspiratory oxygen (Fio₂) as possible while slowly normalizing Paco₂ levels over many hours via permissive hyper-apnea to allow acid-base normalization and avoidance of generation of excessive intrathoracic pressures by high ventilating rates. Hypoxemia and abnormal heart rhythm mandate inpatient care.

64.5. The addition of B-type natriuretic peptide (BNP) to the initial evaluation of patients with acute dyspnea will do which of the following?
A. Be normal in cases of acute pulmonary embolus
B. Help differentiate right from left heart failure in chronic obstructive pulmonary disease (COPD) patients with some degree of heart failure
C. Rarely be helpful
D. Reliably help identify patients whose symptoms are caused by exacerbation of congestive heart failure (CHF)
E. Result in a smaller number of patients being treated for CHF regardless of the cutoff value used

Answer: D. The addition of a BNP level to the evaluation of COPD patients may benefit when taken in the context of the clinical impression. By establishing a cutoff value, the majority of CHF patients will be identified, but at any cutoff, there will be false positives. The BNP cannot differentiate left versus right ventricular stretch and strain and may not be normal in cases of pulmonary embolus because of the right ventricular stretch.

64.6. A 34-year-old man presents with 3 days of severe sore throat and painful swallowing. He reports his symptoms are worsening. His vital signs are: blood pressure, 127/85 mm Hg; heart rate, 132 beats per minute; respiratory rate, 22 breaths per minute; and temperature, 100.8°F (38.2°C). On physical examination, he is sitting upright and is noted to be spitting his saliva into a cup. On lung examination, you note good air movement but inspiratory stridor. The remainder of his physical examination is within normal limits. As you begin preparations for airway management, which antibiotic is appropriate?
A. Amoxicillin
B. Azithromycin
C. Ceftriaxone
D. Doxycycline
E. Rifampin

Answer: C. This patient has epiglottitis by history and physical examination. Adult patients with epiglottitis have higher mortality than pediatric patients, secondary to delayed diagnosis. The most important and time-sensitive intervention is airway management. Once a decision has been made about airway management, it is important to initiate prompt treatment of the infection. *Haemophilus influenzae* is the most commonly isolated bacterial pathogen, and thus treatment should be aimed at this pathogen. Staphylococci, streptococci, and viruses have also been implicated. Ceftriaxone and cefotaxime are commonly used first-line agents. Another option would be medications from the fluoroquinolone class. Up to 50% of *H. influenzae* isolates are resistant to amoxicillin (because of beta-lactamase production). Resistance is also a problem with both azithromycin and doxycycline, so they are not appropriate first-line agents. Although rifampin has activity against *H. influenzae*, resistance develops, and this agent should not be used as monotherapy. After initial coverage, culture and sensitivity results should be used to guide therapy.
PHARYNGITIS (TONSILLOPHARYNGITIS)

Principles

Tonsillopharyngitis—pharyngitis—is an inflammatory syndrome of the oropharynx. Transmission is mainly through contact with respiratory secretions but can also occur through food and fomite contact. Although most cases of pharyngitis are uncomplicated and self-limited, the associated swelling may threaten airway patency or preclude the ingestion of adequate liquids, leading to dehydration. Furthermore, a few causes of pharyngitis can also lead to systemic complications.

Viruses are responsible for most cases of pharyngitis in children and adults. Bacterial causes of pharyngitis include group A beta-hemolytic Streptococcus (GAS), non–group A streptococci, Mycoplasma pneumoniae, Chlamydia pneumoniae, and sexually transmitted diseases. Fusobacterium necrophorum has been increasing recognized as a cause of pharyngitis in adolescents and young adults. Whereas immunization has led to a decline in diphtheria as a cause of pharyngitis, it can result in serious complications and needs to remain in any differential diagnosis. Mixed aerobic and anaerobic bacteria often cause chronic or recurrent pharyngitis, especially those that produce β-lactamase. Epstein-Barr virus (EBV) and Actinomyces are also implicated in chronic or recurrent pharyngitis. Rare causes of bacterial pharyngitis includeFrancisella tularensis, Yersinia pestis, andYersinia enterocolitica.

Clinical Features

Table 65.1 outlines the various causes of pharyngitis and their associated signs, symptoms, and treatment. The most common symptom is pharyngeal pain aggravated by swallowing that may radiate to the ears. Examination usually reveals fever, pharyngeal erythema, pharyngeal or tonsillar exudate, and tonsillar enlargement (Fig. 65.1). The infection tends to localize to lymphatic tissue and produces suppuration and swelling of the tonsils, along with tender cervical adenopathy. Occlusion of the eustachian tubes may result in secondary otitis media. Clinical differentiation of the causative organisms is virtually impossible.

Viral pharyngitis usually occurs in conjunction with cough, rhinorrhea, myalgia, hoarseness, headache, stomatitis, conjunctivitis, exanthem, and odynophagia. Low-grade fever, diarrhea, oral ulcers, and pharyngeal edema, erythema and exudates may be present. Cervical lymphadenopathy is generally absent. Systemic viral infections, including measles, cytomegalovirus (CMV), rubella, and human immunodeficiency virus (HIV), may initially manifest as mild pharyngitis. HIV and CMV pharyngitis may be clinically indistinguishable from infectious mononucleosis.

Influenza occurs in epidemics and is associated with high fever, myalgia, and headache. Although 50% to 80% of patients with influenza experience pharyngeal discomfort, pharyngeal exudate and cervical lymphadenopathy are rare. Adenovirus may cause severe exudative pharyngitis with cervical adenitis similar to that in streptococcal pharyngitis. Of cases of adenoviral pharyngitis, 30% to 50% are associated with a follicular, usually unilateral, conjunctivitis and preauricular lymphadenopathy. Coxsackieviruses are the most frequent causes of hand-foot-and-mouth disease and herpangina.

Pharyngitis is a common manifestation of infectious mononucleosis (caused by EBV) in young adults. Symptoms develop after an incubation period of 4 to 7 weeks. Fever and a tonsillar exudate or a cheesy or creamy white membrane is often present. Cervical as well as generalized lymphadenopathy (90%–100%) and splenomegaly (50%) are usually noted, and palatal petechiae may be present. Hepatomegaly is present in 10% to 15% of cases. Periorbital edema and rash are rare findings. In up to 90% of patients with mononucleosis who are given ampicillin or amoxicillin, a diffuse macular rash develops that may be misdiagnosed as an allergic reaction.

Patients with early (days to weeks) HIV infection can develop an acute retroviral syndrome. This is manifested by fever, sore throat, generalized nontender lymphadenopathy, diffuse maculopapular rash, arthralgias, mucocutaneous ulcerations and, commonly, diarrhea. Nonexudative pharyngitis is present in 50% to 70% of patients. Oral thrush and ulcers may be present. Acute HIV infection can be differentiated from infectious mononucleosis by a more acute presentation, absence of tonsillar hypertrophy or exudates, frequent occurrence of rash, and presence of oral ulcerations.

Herpes simplex pharyngitis, which typically affect young adults, manifests with the presence of painful vesicles with erythematous bases. Ulcers may be present on the pharynx, lips, tongue, gums, and buccal mucosa. Pharyngeal erythema and exudate, fever, and tender lymphadenopathy are common for 1 to 2 weeks. In an immunocompromised host, large painful ulcers may be present. Herpes pharyngitis can be caused by primary infection or reactivation. Concomitant bacterial superinfection may occur. GAS pharyngitis as a disease of children 5 to 15 years old and, in temperate climates, occurs in winter and early spring. It is responsible for 5% to 15% of cases of pharyngitis in patients older than 15 years and is rare in patients younger than 3 years. In epidemics, amongst persons in semiclosed communities and within families of index cases, the incidence may double. GAS pharyngitis is associated with sudden-onset sore throat, temperature over 38.3°C (101°F), tonsillar erythema and exudates, palatal and uvular petechiae (Fig. 65.2), uvular edema and erythema, and tender anterior cervical lymphadenopathy. Headache, nausea, vomiting, and abdominal pain may be present. GAS pharyngitis associated with a fine sandpaper erythematous rash that subsequently desquamates is termed scarlet fever. These findings, however, cannot be used to diagnose or exclude streptococcal pharyngitis reliably. Patients with recent exposure to others at risk for GAS pharyngitis or in whom it has been diagnosed are more likely to become infected. Non-GAS species can cause pharyngitis indistinguishable from GAS. Groups C and G streptococci can cause epidemic foodborne pharyngitis.

Diphtheria is a potentially lethal cause of pharyngitis that is uncommon where adequate vaccinations are administered. US serologic surveys have indicated that a large percentage of adults...
and adolescents lack immunity to diphtheria toxin. After a 2- to 4-day incubation period, patients develop malaise, sore throat, fever, and dysphagia. Examination early in the disease process may reveal pharyngeal erythema and isolated spots of gray or white exudate that later coalesce to form a pseudomembrane. This gray-green pseudomembrane is usually well demarcated and covers the nares, tonsils, soft palate, pharyngeal mucosa and, occasionally, the uvula. The membrane may extend to involve the larynx and tracheobronchial tree, leading to hoarseness, cough, stridor, and airway obstruction. Severe inflammation and edema can produce dysphonia and a characteristic so-called bull neck appearance. Some strains of *Corynebacterium diphtheriae* produce a systemic toxin that may cause myocarditis, polyneuritis (at first autonomic and then peripheral), vascular collapse, diffuse focal organ necrosis, and death. Asymptomatic carriers may transmit the disease. *Corynebacterium ulcerans* is an animal pathogen transmitted by the consumption of raw milk that can produce infection indistinguishable from that caused by *C. diphtheriae*.

that strongly mimics diphtheria; it is also associated with chronic tonsillitis.  

Anaerobic pharyngitis, or Vincent’s angina, is characterized by superficial ulceration and necrosis that often results in the formation of a pseudomembrane. Foul-smelling breath, odynophagia, submandibular lymphadenopathy, and exudate are often present. Patients typically have poor oral hygiene.  

Gonococcal pharyngitis is a sexually transmitted disease that may occur independently of genital infection. Those at highest risk are persons who practice receptive oral sex, especially men who have sex with men. Its severity is variable and may result in an exudative or nonexudative pharyngitis. These differing manifestations occur after a latent period of infection. Asymptomatic carriers are described, as is chronic and recurrent pharyngitis. Gonococcal pharyngitis is an important source of gonococcemia.  

Syphilitic pharyngitis is a manifestation of primary or tertiary syphilis and manifests with painless mucosal lesions. *Chlamydia trachomatis* pharyngitis is a sexually transmitted disease that manifests similarly to gonococcal pharyngitis and is associated with orogenital sex. Urogenital culturing is necessary, along with treatment of sexual contacts. Patients are usually asymptomatic or may have only mild symptoms.  

Tuberculous pharyngitis usually occurs in patients with advanced disease. Symptoms and signs include hoarseness and dysphagia with pharyngeal ulcerations. Candidal pharyngitis is usually found in immunocompromised adults. Patients have dysphagia, odynophagia, and adherent white plaques with focal bleeding points.  

*Mycoplasma pneumoniae* infection usually causes a mild pharyngitis. *Mycoplasma* infection occurs in epidemics and in crowded conditions and can be responsible for approximately 10% of cases of adult pharyngitis. Pharyngeal and tonsillar exudates, cervical lymphadenopathy, and hoarseness are common. Lower respiratory tract infection may also be present.  

*C. pneumoniae* pharyngitis resembles *M. pneumoniae* pharyngitis. It also occurs in epidemics or crowded conditions. Severe pharyngitis with laryngitis is suggestive of *C. pneumoniae* infection. Swelling and pain in the deep cervical lymph nodes may be prominent. Lower respiratory tract and concomitant sinusitis occur. The hallmarks of chlamydial pharyngitis are recurrence and persistence.  

*Fusobacterium* pharyngitis presents in a manner similar to GAS, primarily in patients aged 10 to 49 years.  

Although most cases of pharyngitis follow a benign course, life-threatening complications can occur. Airway compromise from tonsillar enlargement, local and distant spread of infection, deep neck abscesses, necrotizing fasciitis, sleep apnea, bacteremia, sepsis, and death have been reported but are very rare.  

Infectious mononucleosis may lead to hepatic dysfunction, splenic injury, neurologic disorders, pneumonitis, pericarditis, and hematologic disorders, including thrombocytopenia and hemolytic anemia. Complications of GAS pharyngitis are suppurative and nonsuppurative. Suppurative complications include peritonsillar abscess, deep space abscesses, cervical lymphadenitis, otitis media, sinusitis, mastoiditis, bacteremia, sepsis, osteomyelitis, empyema, meningitis, and soft tissue infections. Nonsuppurative complications include scarlet fever, rheumatic fever, poststreptococcal glomerulonephritis, nonrheumatic perimyocarditis, erythema nodosum, and streptococcal toxic shock syndrome. In contrast to rheumatic fever, other complications of GAS pharyngitis have been increasing in incidence and severity. A chronic carrier state of streptococcal infection exists and can persist for several months, despite treatment. Affected patients are asymptomatic, at low risk for rheumatic fever, and not considered highly contagious. Non–group A streptococcal pharyngitis may be complicated by the same suppurative complications as group A infections. Scarlet fever and acute glomerulonephritis, but not rheumatic fever, are linked to groups C and G pharyngitis.  

### Diagnostic Considerations

#### Differential Diagnosis

The differential diagnosis of pharyngitis includes epiglotitis, tracheitis, lingual tonsillitis, parapharyngeal abscess, retropharyngeal and other deep space abscesses and cellulitis of the neck, tumors, allergic reactions, Stevens-Johnson syndrome, drug reactions, angioneuroptic edema, chemical and thermal burns, esophagitis, gastroesophageal reflux disease, thyroiditis, cricoarytenoid arthritis, and foreign bodies.  

#### Diagnostic Testing

The Monospot test has a sensitivity of approximately 85% and a specificity of almost 100%; however, results may be falsely negative in up to 10% of patients with infectious mononucleosis in the early stages of the illness. Immunoglobulin M (IgM) antibodies to EBV capsid antigen develop in 100% of cases. EBV nuclear antigens develop within 3 to 6 weeks and are useful if an initially negative test result becomes positive at a later date. Peripheral blood smears demonstrate atypical mononuclear cells in 75% of patients, with the peak incidence occurring in the second to third weeks of illness. The test may be ordered when the patient has failed treatment for GAS pharyngitis or when posterior cervical lymphadenopathy predominates.  

Herpes pharyngitis may be diagnosed by culture, cytopathologic tests on scrapings of lesions, and serologic tests. Enzyme-linked immunosorbent assay testing for HIV can be falsely negative during the first 3 to 4 weeks of illness. During this period, quantitative assays for plasma RNA should be performed.  

Several authors have proposed scoring systems for diagnosing GAS pharyngitis based on clinical findings. Clinical scoring is most accurate in identifying patients at low risk for GAS pharyngitis. Antistreptolysin O titers are not recommended for the diagnosis of routine GAS pharyngitis. A single throat culture has a sensitivity of 90% to 95% in detecting *Streptococcus pyogenes* in the pharynx. Variables that affect the accuracy of throat cultures include collection and culturing techniques and the recent use of antibiotics.  

Rapid diagnostic tests for GAS detect streptococcal antigens. Rapid streptococcal tests (RSTs) have a reported specificity and sensitivity of up to 95%. Sensitivity and specificity in actual practice are lower than in controlled trials. Using RSTs in patients without clinical findings consistent with GAS increases false-positive results. A positive RST result seems to indicate the presence of *S. pyogenes* in the pharynx reliably and does not require backup culture. Patients with positive cultures or RSTs may actually be carriers (5%–15% of cases) who may not need treatment and are at low risk for transmission and complications. In contrast, RST results are often negative in the setting of pharyngitis with a low bacterial count. Although it is recommended that a negative RST result in a child be followed by a confirmatory culture, adults with negative RST results do not require confirmatory cultures because of the lower incidence of GAS infection and extremely low risk for complications. Neither testing nor antibiotic treatment should be used in adults who are clinically at low risk for GAS infection, especially patients who have symptoms associated with a viral pharyngitis, including cough, rhinorrhea, hoarseness, oral ulcers, stomatitis, and conjunctivitis.  

We recommend the use of clinical criteria in conjunction with RSTs for the diagnosis of GAS pharyngitis. The Centor criteria (Box 65.1) is a useful, validated clinical tool for adults but is not useful for diagnosing GAS pharyngitis in children. Adults who present with none or only one Centor criterion should not be tested or treated; patients with all four criteria should be treated without testing. Patients with two or three criteria should undergo...
Pharyngitis caused by other treatable organisms should also be considered. Non–group A streptococcal pharyngitis should also be treated because the same suppurative complications occur as with group A streptococcal pharyngitis. Confirmation of diphtheria requires culturing on the proper media and immunologic testing (polymerase chain reaction assay), and toxigenicity testing should also be performed. The diagnosis of A. haemolyticum infection should be considered if a rash, including erythema multiforme, accompanies pharyngitis. The diagnosis of Vincent’s infection should be considered if a rash, including erythema multiforme, accompanies pharyngitis. The diagnosis of Vincent’s infection may have been noncompliant, acquired a new infection (at times from asymptomatic close contacts), or could be chronic carriers of GAS who are experiencing repeat viral infections. With actual recurrent GAS infections, treatment should be with IM penicillin. Alternative antibiotics for recurrent infections include cefdinir, cefpodoxime, amoxicillin-clavulanate, and clindamycin. Further recurrences require more extensive evaluation, and pharyngeal cultures should be obtained and consideration given to evaluating and treating close contacts for GAS infection.

The successful treatment of diphtheria is inversely related to disease duration. When diphtheria is strongly suspected based on clinical findings, patients should be placed in respiratory droplet isolation and antitoxin (a horse serum product) treatment begun empirically. The dose of antitoxin varies widely and depends on the site of infection and duration of symptoms. Antibiotics have little effect on the resolution of systemic toxicity but are useful in eradicating C. diphtheriae infection and preventing transmission. The antibiotic of choice is penicillin G followed by penicillin VK, when able to tolerate oral antibiotics, for a total of 10 days, or erythromycin 500 mg/day for 10 days, is also effective in eradicating the carrier state of C. diphtheriae and treating erythromycin-resistant diphtheria. Close contacts should be cultured and treated with penicillin G or erythromycin 500 mg qid for 10 days. Diphtheria toxoid should be administered during convalescence and to unvaccinated close contacts.

Candidal pharyngitis is treated with systemic fluconazole or itraconazole. Alternative therapy includes nystatin ( suspension or tablets) or oral clotrimazole for 14 days. Chronic suppression therapy with fluconazole may be required for HIV pharyngitis.

RSTs and be treated only if they have positive results (Table 65.2). This approach may lead to some overtreatment with antibiotics. These recommendations apply only to immunocompetent patients without comorbidities or a history of rheumatic fever. They do not apply in settings of outbreaks of GAS infection or rheumatic fever, nor are they appropriate where the endemic rate of rheumatic fever is higher than that in the United States.

**Management**

Patients with pharyngitis should be treated symptomatically with topical anesthetic rinses or lozenges and acetaminophen or ibuprofen. Oral hydration and saltwater gargles are helpful. Most cases of pharyngitis are self-limited and follow a benign course. Antibiotics are not indicated in the vast majority of cases of pharyngitis diagnosed in the United States.

Treatment of infectious mononucleosis is supportive (see Chapter 130). Patients should avoid contact sports for 6 to 8 weeks to minimize the small risk of splenic rupture. Corticosteroids are indicated for patients with tonsillar hypertrophy that threatens airway patency, severe thrombocytopenia, or hemolytic anemia. Steroids should be used cautiously in children and in only those with documented GAS infections. GAS pharyngitis is primarily a disease of children 5 to 15 years of age. In adults, GAS is a self-limited illness that lasts 3 to 4 days. The rationale for treating streptococcal pharyngitis is that antibiotics decrease suppurative and nonsuppurative complications, shorten the course of illness by about 1 day, and decrease transmission. Patients are no longer infectious after 24 hours of antibiotic treatment, and persistent symptoms lasting beyond a few days are suggestive of suppurative complications. GAS pharyngitis should be treated adequately (within 9 days) to prevent rheumatic fever, which is rare in the United States and complicates 0.3% of cases of GAS pharyngitis but, in epidemics, the incidence increases to 3%. The incidence and course of poststreplococcal glomerulonephritis caused by nephritogenic strains are unaffected by antibiotic therapy.

The antibiotic regimen of choice for adults with GAS pharyngitis is a single intramuscular (IM) injection of 1.2 million units of benzathine penicillin or a 10-day course of penicillin V, 500 mg orally bid. IM penicillin may be more effective than oral penicillin and ensures compliance, but allergic reactions are more severe as a result of procaine allergy, and treatment is more expensive. Penicillin failure usually reflects noncompliance, reinfection, or the presence of β-lactamase–producing organisms. Clarithromycin, cephalosporins, or clindamycin for 10 days, or a 5-day course of azithromycin, is recommended for patients who are allergic to penicillin. Adjunctive therapy with corticosteroids has been shown to shorten the duration and severity of symptoms somewhat in patients with GAS. Single-dose dexamethasone has been shown to be helpful in adults and children.

Patients whose symptoms return within a few weeks of treatment may have been noncompliant, acquired a new infection (at times from asymptomatic close contacts), or could be chronic carriers of GAS who are experiencing repeat viral infections. With actual recurrent GAS infections, treatment should be with IM penicillin. Alternative antibiotics for recurrent infections include cefdinir, cefpodoxime, amoxicillin-clavulanate, and clindamycin. Further recurrences require more extensive evaluation, and pharyngeal cultures should be obtained and consideration given to evaluating and treating close contacts for GAS infection.
Treatment of recurrent or chronic tonsillitis should include β-lactamase–resistant antibiotics active against aerobic and anaerobic organisms. Choices include oral cephalosporins, amoxicillin-clavulanic acid, penicillin with rifampin or metronidazole, and clindamycin.56

Steroids given in conjunction with oral antibiotics in adults with acute pharyngitis may significantly shorten the duration of symptoms and provide a greater degree of pain relief without increasing complications. Oral (40–60 mg of prednisone/day for 1–5 days) or IM (single dose of 10 mg of dexamethasone) administration is equally effective.56

Disposition
The vast majority cases of pharyngitis follow an uncomplicated course, and patients can be treated on an outpatient basis. The presence of local (airway) and systemic complications should prompt consultation with an otolaryngologist, and possibly an infectious disease specialist, and will often lead to hospital admission.

LINGUAL TONSILLITIS

Principles
Lingual tonsillitis is a rarely diagnosed cause of pharyngitis that predominantly occurs in patients who have had their palatine tonsils removed. The lingual tonsils are usually (size and location are highly variable) located symmetrically on either side of the midline, just below the inferior pole of the palatine tonsils and anterior to the vallecula at the base of the tongue. This lymphoid tissue may enlarge after puberty, repeated infection, and tonsillectomy.

Clinical Features
Patients with lingual tonsillitis have a sore throat that worsens with movement of the tongue (including tongue depression) and phonation. The patient may have a classic so-called hot potato voice—the muffled voice one has when eating very hot food—and report feeling a swelling in the throat. Dysphagia, fever, respiratory distress, and stridor may be present. Chronic or recurrent lingual tonsillitis may also cause a chronic cough or sleep apnea. Physical findings often include a normal-appearing pharynx with mild hyperemia.

Diagnostic Considerations
Differential Diagnosis
The differential diagnosis is similar to that mentioned for adult pharyngitis.

Diagnostic Testing
Plain lateral radiographs of the neck are helpful in the diagnosis of lingual tonsillitis (Fig. 65.3). Computed tomography (CT) scanning and direct visualization with laryngoscopy may also help clarify the diagnosis.

Management
Management includes maintenance of airway patency, antibiotics, and supportive therapy. Rarely, acute lingual tonsillitis may be a life-threatening condition. Airway management includes warmed humidified oxygen, hydration, and corticosteroids. Nebulized epinephrine can relieve the acute respiratory distress and stridor.

Fig. 65.3. Lingual tonsillitis. Note the scalloped appearance of the lingual tonsil on the anterior surface of the vallecula (arrows), with a normal epiglottis and aryepiglottic fold.

LARYNGITIS

Principles
Laryngitis is a common inflammatory condition which, when infectious, is almost always caused by a viral infection. There are numerous causes of noninfectious laryngitis, including acid reflux disease, trauma, chemical and thermal burns, overuse of the vocal cords, and allergies.

Clinical Features
Laryngitis generally is a benign viral illness, with peak symptoms lasting 3 to 4 days. Patients present with dysphonia. Fever, throat pain, dysphagia, coughing, and myalgia may also be present. Patients may develop chronic laryngitis.

Diagnostic Considerations
Differential Diagnoses
The differential diagnosis is similar to that mentioned for pharyngitis.

Management
Although voice rest is recommended, there is no evidence that this is of any benefit in terms of duration or severity of symptoms. Proton pump inhibitors are useful in treating laryngitis and chronic laryngitis due to esophageal reflux disease. Antibiotics are not indicated unless signs of bacterial infection are present.5 Steroids may hasten the resolution of symptoms.9

Disposition
Laryngitis is a self-limiting disease treated on an outpatient basis.
ADULT EPIGLOTTIS

Principles

Adult epiglottitis can lead to rapid, unpredictable airway obstruction. Although the incidence of pediatric epiglottitis has diminished since the introduction of *Haemophilus influenzae* vaccine, there has been an increase in cases of adult epiglottitis.5,10 Adult epiglottitis is a localized cellulitis involving the supraglottic structures, including the base of the tongue, vallecula, aryepiglottic folds, arytenoid soft tissues, lingual tonsils, and epiglottis. Inflammation does not extend to the infraglottic regions. Some adults have a normal epiglottis in the setting of severe supraglottic involvement; thus, the term supraglottitis may be a more accurate description. Adults with epiglottic involvement are prone to epiglottic abscesses.10

Adult epiglottitis can be caused by many viral, bacterial or, rarely, fungal pathogens, but the most commonly isolated bacterial pathogen is *H. influenzae* type b, which is associated with a more aggressive disease course. The predominant organisms isolated from epiglottic abscesses are *Streptococcus* and *Staphylococcus* spp. Adult epiglottitis may also result from thermal injury.10

Clinical Features

Adult epiglottitis has no age or seasonal prevalence. Males and smokers are more commonly affected. Adults with epiglottitis typically experience a prodrome resembling that of a benign upper respiratory tract infection. The duration of the prodrome is usually 1 to 2 days but may be as long as 7 days or as short as several hours. Patients who have a rapid onset of the disease, as well as those with comorbid conditions (especially diabetes), are more likely to require airway intervention.10

Patients typically have dysphagia, odynophagia, and a sore throat. Pain may be severe, and the suspicion of epiglottitis is raised when the patient reports severe symptoms of pharyngitis and has obvious odynophagia or dysphagia but examination of the oral pharynx and tonsils shows only minimal or no signs of inflammation or exudate. Dysphonia and a muffled voice are common, whereas hoarseness is unusual. Fever is absent in up to 50% of cases and may develop only in the later stages of the disease. Concomitant uvulitis, pharyngitis, tonsillitis, Ludwig's angina, peritonsillar abscess, and parotitis can occur. Tenderness to palpation of the anterior aspect of the neck in the region of the hyoid and when the larynx is moved side to side is a suggestive finding in epiglottitis.

Diagnostic Considerations

Differential Diagnosis

The differential diagnostic considerations are similar to those listed for pharyngitis.

Diagnostic Testing

When epiglottitis is suspected, visualization of the epiglottis is indicated. Necessary equipment to provide bag-mask ventilation, intubation, or cricothyrotomy must be immediately available. In patients with respiratory distress, drooling, aphonia, or stridor, it is important that the patient be maintained in a position of comfort. Airway examination is undertaken as soon as equipment has been obtained and requires a double setup, with the ability to proceed immediately to cricothyrotomy.10 Depending on the perceived urgency of the airway examination, preparations should include a drying agent, preferably glycopyrrolate, 0.2 mg intravenously (IV), topical anesthesia (eg, 4% lidocaine by atomizer, after the glycopyrrolate has reduced secretions), and light sedation (eg, midazolam in 1-mg increments, often with small doses [50-µg increments] of fentanyl). Laryngospasm and complete obstruction can occur during instrumentation of the inflamed airway. Flexible laryngoscopy is the preferred approach because it provides direct, minimally invasive examination of the upper airway and intubation, if planned in advance, can be completed over the laryngoscope. Laryngoscopy reveals a swollen epiglottis and surrounding structures (Fig. 65.4). The epiglottis may appear cherry red but is often pale and edematous. Although lateral cervical soft tissue radiographic films have a sensitivity of up to 90% when compared with the gold standard of laryngoscopy, radiographs are not a substitute for visualization of the upper airway structures by flexible or rigid laryngoscopy. Patients with severe pain, altered voice, complaints of dyspnea, or inability to swallow secretions are at risk for sudden airway obstruction; they should undergo prompt upper airway examination and should not be sent to radiology for x-ray examination. Radiologic findings, when present, include obliteration of the vallecula, swelling of the arytenoids and aryepiglottic folds, edema of the prevertebral and retropharyngeal soft tissues, and ballooning of the hypopharynx and mesopharynx. The edematous epiglottis appears enlarged and thumb-shaped (Fig. 65.5). An epiglottic width greater than 8 mm or aryepiglottic fold width greater than 7 mm is suggestive of epiglottitis. Adults with suspected epiglottitis and normal soft tissue radiographic films should undergo laryngoscopy. Similarly, patients determined to have epiglottitis by radiography also require upper airway examination by laryngoscopy to determine the extent of airway compromise and the need for intubation.

Management

Unlike in the pediatric population, most cases of adult epiglottitis can be managed without intubation or tracheostomy. Antibiotic therapy and intensive care support until symptoms resolve is the cornerstone of therapy in these patients. Airway management is indicated for less than 15% of patients and should be considered for those with symptoms and signs of imminent airway obstruction. Symptoms of severe disease that may require rapid airway intervention include tachycardia disproportionate to fever, tachypnea, stridor, shortness of breath, and rapid onset of symptoms. Patients who are spitting, drooling, or unable to swallow their own saliva, and patients who assume a classic sniffing position, should
be considered to be at imminent risk for rapid airway obstruction. These patients should not be laid flat, and immediate preparations should be made to secure the airway rapidly (see Chapter 1). In patients with a rapidly progressive course, such as those whose symptoms have increased greatly in severity over 4 to 6 hours, even with only moderate laryngoscopic findings, preventive intubation is indicated because progression of swelling and airway compromise can occur rapidly and with little warning. Intubation also is undertaken, despite only moderate findings on laryngoscopy, for patients who are immunocompromised or diabetic or have an epiglottic abscess.

All patients with epiglottitis should be treated with extreme care because of the possibility of unpredictable sudden airway obstruction. Endotracheal intubation should be performed under direct visualization. Awake flexible endoscopic intubation is the optimal method, but awake orotracheal intubation by direct laryngoscopy or videolaryngoscopy also can be done. Blind nasotracheal intubation can lead to airway obstruction and is contraindicated in the setting of epiglottitis.

Antibiotics should be initiated against *H. influenzae* and other likely bacterial pathogens. First-line agents pending culture and sensitivity results are cefotaxime and ceftriaxone plus vancomycin. Alternative antibiotics include levofloxacin plus clindamycin. The role of steroids is unresolved, but racemic epinephrine is used only as a temporizing measure while preparations are made to secure the airway because short-term use can produce improvement, only to be followed by a rebound effect, in which the symptoms and signs revert to their pretreatment level of severity or become even worse. For patients admitted to the hospital, consultation with an otolaryngologist should be arranged.

**Disposition**

If upper airway endoscopy shows mild or moderate disease, with preservation of a widely patent airway, and the patient’s symptoms have developed gradually over a longer period of time (ie, 24 hours), treatment with IV antibiotics, parenteral opioid analgesia, and humidified oxygen in a monitored inpatient unit (often the intensive care unit [ICU]) or an emergency department (ED) observation unit is appropriate, providing the patient is without dyspnea and can handle his or her secretions. Laryngoscopy is repeated in 6 to 12 hours to ensure that the patient’s condition is improving and to determine readiness for discharge.

**PERITONSILLITIS (PERITONSILLAR CELLULITIS AND PERITONSILLAR ABSCESS)**

**Principles**

Peritonsillitis may occur as a result of acute tonsillitis. Infection in Weber’s glands or the tonsillar crypts invades the peritonsillar tissues and thereby leads to cellulitis and abscess formation. Fibrous fascial septae divide the peritonsillar space into compartments and direct the infection anteriorly and superiorly.

Dental infections, chronic tonsillitis, infectious mononucleosis, smoking, chronic lymphocytic leukemia, and tonsilloliths are predisposing factors. Peritonsillar abscess occurs in patients who have undergone complete tonsillectomy and is seen in all age groups. Peritonsillitis recurs in up to 50% of patients, with the incidence of recurrent peritonsillar abscess approximately 10%. The highest incidence of recurrence is seen in patients younger than 40 years and in those with a history of chronic tonsillitis.

Most peritonsillar abscesses are polymicrobial. *Fusobacterium necrophorum* is common. β-Lactamase–producing organisms are isolated more commonly in patients who have received prior antibiotics.

**Clinical Features**

There is often a delay of 2 to 5 days between abscess formation and local and systemic symptoms. Symptoms and signs include odynophagia, dysphagia, drooling, trismus, and referred otalgia. Patients may have a characteristic muffled, hot potato voice, and rancid breath. Systemic manifestations include fever, malaise, and dehydration. Patients may relate a history of recurrent tonsillitis.

The examination of the pharynx can be limited by trismus. Physical findings of peritonsillitis include inflamed and erythematous oral mucosa, purulent tonsillar exudates that obscure the tonsil, and tender cervical lymphadenopathy. Peritonsillar cellulitis may be a precursor of and mimics peritonsillar abscess. Peritonsillar abscess is characterized by a greater frequency of drooling, trismus, and dysphagia, whereas peritonsillar cellulitis is usually bilateral. The distinguishing feature of peritonsillar abscess is inferior medial displacement of the infected tonsil (at times involving the soft palate), with contralateral deviation of the uvula (Fig. 65.6). The abscess is generally unilateral and located in the superior pole of the tonsil. Bilateral peritonsillar abscesses occur occasionally.

**Diagnostic Considerations**

**Differential Diagnosis**

The differential diagnosis of peritonsillitis includes hypertrophic tonsillitis, infectious mononucleosis, tubercular granuloma, diphtheria, other deep space infections of the neck, cervical adenitis, carotid artery aneurysms, foreign bodies, and neoplasms.

**Diagnostic Testing**

Aspiration of pus establishes the diagnosis of peritonsillar abscess. Because patients with peritonsillar abscess have a 20% incidence
of mononucleosis, laboratory testing for mononucleosis should be considered when systemic symptoms or findings of mononucleosis are present (see Chapter 122.) Radiographs are of no value when the clinical examination identifies peritonsillar abscess. Although contrast-enhanced CT and ultrasonography (intraoral and transcervical) aid in differentiating peritonsillar abscess from cellulitis, especially when patients are unable to cooperate with needle aspiration, these rarely, if ever, are required.6

Management

Needle aspiration is indicated when an abscess is present or suspected. Antibiotics alone may suffice with peritonsillar cellulitis. Regimens include piperacillin-tazobactam or high-dose ceftriaxone plus metronidazole. Alternative antimicrobial agents include clindamycin, cefoxitin, ampicillin-sulbactam, a carbapenem, high-dose penicillin and rifampin, or ticarcillin-clavulanate. The use of steroids are also beneficial.13

Drainage of an abscess is usually curative. Needle aspiration of abscesses by emergency clinicians and otolaryngologists is diagnostic, although false-negative aspirations occur in approximately 10% of cases, and another 10% may require repeated aspirations, and therapeutic. This immediately relieves symptoms and is more cost-effective, less painful, and easier to perform than incision and drainage. Intraoral ultrasound-guided needle aspiration is a useful adjunct in the presence of trismus.13

Disposition

Hospital admission rarely is indicated but is considered for patients who have significant comorbidity, appear toxic, or are unable to tolerate oral fluids or whose pain is not managed by oral analgesics. Most patients can be observed for 4 to 6 hours after aspiration in the ED observation unit or ED who are receiving antibiotics, IV hydration, and analgesia. The most dangerous immediate complication of peritonsillitis is pharyngeal obstruction with upper airway compromise. Other very rare complications include sepsis, abscess rupture, and pulmonary aspiration leading to pneumonia, empyema, and pulmonary abscess formation. Infection can spread contiguously to the parapharyngeal and retropharyngeal spaces. Ludwig’s angina, mediastinal involvement (including mediastinitis, pneumonia, empyema, and pericarditis), myocardiitis, carotid artery erosion, jugular vein thrombophlebitis, septic embolization, abscess formation, Lemierre’s syndrome (see later, “Parapharyngeal Abscess”), and cervicothoracic necrotizing fasciitis can complicate peritonsillitis. The intracranial extension of peritonsillitis may result in meningitis, cavernous sinus thrombosis, and cerebral abscess.

LUDWIG’S ANGINA

Principles

Ludwig’s angina is a potentially fulminant disease process that can lead to death within hours. This is a progressive cellulitis of the connective tissues of the floor of the mouth and neck that begins in the submandibular space, comprised of the sublingual and submaxillary spaces. Dental disease is the most common cause of Ludwig’s angina. An infected or recently extracted lower molar is noted in most affected patients. Other causes of Ludwig’s angina include a fractured mandible, foreign body or laceration in the floor of the mouth, tongue piercing, traumatic intubation and bronchoscopy, secondary infections of an oral malignancy, osteomyelitis, submandibular sialadenitis, peritonsillar abscess, furuncles, infected thyroglossal cysts, and sepsis.

Clinical Features

Infection of the sublingual and submaxillary spaces leads to edema and soft tissue displacement, which may result in airway obstruction. The most common presentation in patients with Ludwig’s angina includes dysphagia, odynophagia, neck swelling, and neck pain. Other symptoms and signs include dysphonia, hot potato voice, dysarthria, drooling, tongue swelling, pain in the floor of the mouth, restricted neck movement, and sore throat. Patients should be questioned regarding recent dental extraction and disease. The rapid development of crepitus and unilateral pharyngitis in patients with a recent dental extraction should suggest the diagnosis of Ludwig’s angina.

The most common physical findings in Ludwig’s angina are bilateral submandibular swelling and elevation or protrusion of the tongue. Other findings include elevation of the floor of the mouth, posterior displacement of the tongue, and a woody consistency of the floor of the mouth. The combination of tense edema and brawny induration of the neck above the hyoid may be present, described as a bull neck. Marked tenderness to palpation of the neck and subcutaneous emphysema may be noted. Usually, trismus and fever are present, but there is no palpable fluctuance or cervical lymphadenopathy. Tenderness to percussion may be elicited over the involved teeth.

Diagnostic Considerations

Differential Diagnosis

The differential diagnosis includes deep cervical node suppuration, peritonsillar and other deep neck space abscess, parotid and submandibular gland abscess, oral carcinoma, angioedema, submandibular hematoma, and laryngeal diphtheria.

Diagnostic Testing

The diagnosis is made clinically. Soft tissue plain films of the neck may confirm the diagnosis by identifying swelling of the affected area and airway narrowing and gas collections but, in general, are not of value. CT and magnetic resonance imaging (MRI) can identify deep space neck infections and airway compromise. Ultrasonography is also useful in diagnosing abscesses and edema in the setting of Ludwig’s angina.

Management

Sudden asphyxiation is the most common cause of death in patients with Ludwig’s angina. Stridor, tachypnea, dyspnea, inability to handle secretions, and agitation all suggest impending airway compromise. Flexible endoscope–guided oral or nasal
intubation under sedation with topical anesthesia is the preferred method of airway control. Direct laryngoscopy can be particularly difficult because of the inability to retract the tongue into the submandibular space and posterior and cephalad displacement of the tongue by the infection. There have been no reports reporting the use of videolaryngoscopes in this condition. Emergent tracheostomy may be necessary in patients with Ludwig’s angina if flexible endoscopic intubation cannot be accomplished. Cricothyrotomy may be technically difficult due to anatomic distortion and opens tissue planes that increase the risk of spreading infection into the mediastinum.14

Emergent high-dose IV antibiotic regimens include piperacillin-tazobactam, ticarcillin-clavulanate, and high-dose penicillin plus metronidazole. Clindamycin can be used in penicillin-allergic patients. Vancomycin should be added if the initial Gram stain reveals gram-positive cocci.6 With the exception of dental extractions, surgery is reserved for patients who do not respond to medical therapy and those with crepitus and purulent collections.

Disposition

All patients with Ludwig’s angina require admission to the ICU and parenteral antibiotics. The mortality rate associated with Ludwig’s angina is less than 10% with early aggressive antibiotic therapy and adequate protection of the airway.

RETROPHARYNGEAL ABSCESS

Principles

The retropharyngeal space lies in the midline and extends from the base of the skull to the superior mediastinum (at about the level of T2). Retropharyngeal abscesses tend to occur laterally to the midline. Posterior to the retropharyngeal space lies the so-called danger space, which extends from the base of the skull to the diaphragm. The prevertebral space extends from the base of the skull to the coccyx. Danger space and prevertebral abscesses are located in the midline. Infections in the retropharyngeal, danger, and prevertebral spaces easily access the mediastinum, which allows the rapid spread of infection and life-threatening complications (Fig. 65.7). Infection may spread from one deep space to another, and patients may present with concomitant deep space infections.15 Retropharyngeal swelling reflects expansion of the retropharyngeal, danger, or prevertebral space. This discussion refers to infections in these spaces collectively as retropharyngeal abscesses.

Retropharyngeal abscess is an uncommon condition that previously was a disease of childhood, with 96% of cases occurring in patients younger than 6 years. In adult patients, who are now increasingly affected, cellulitis develops in the retropharyngeal area. Once the retropharyngeal space is involved, the infection spreads rapidly and an abscess forms. Nasopharyngitis, otitis media, parotitis, tonsillitis, peritonsillar abscess, dental infections and procedures, upper airway instrumentation, endoscopy, lateral pharyngeal space infection, and Ludwig’s angina are all implicated in the development of retropharyngeal abscesses.15 Other causes include blunt and penetrating trauma (usually from foreign bodies, commonly fish bones), ingestion of caustic substances, vertebral fractures, and hematologic spread from distant infection. Vertebral osteomyelitis and diskitis may also lead to infection of the prevertebral space.

Retropharyngeal abscesses are usually polymicrobial, with a mixture of aerobes and anaerobes. β-Lactamase–producing organisms are present in two-thirds of the cases. Tuberculosis is rarely reported in the United States as a cause of retropharyngeal abscess. Staphylococcus is the most common cause of pyogenic vertebral osteomyelitis, leading to the formation of retropharyngeal abscess. Disseminated coccidioidomycosis may also cause retropharyngeal abscess.15

Clinical Features

Patients typically have a sore throat, dysphagia, odynophagia, drooling, muffled voice, neck stiffness, pain, and fever. Dysphonia is usually present and is described as a duck quack (cri du canard). Patients may report feeling a lump in the throat; those with a retropharyngeal abscess may appear quite ill and generally prefer to hold their necks extended and remain in the supine position. This position keeps the swollen posterior pharynx from compressing the upper airway. Forcing the patient to sit may lead to increased dyspnea.15

Physical examination may reveal tender cervical lymphadenopathy and cervical musculature, neck swelling, torticollis, and high fever. Trismus may be present and makes visualization of the pharynx difficult. With retropharyngeal cellulitis, diffuse edema and erythema of the posterior pharynx are present. Once an abscess has developed, palpation may demonstrate a unilateral mass if the retropharyngeal space is affected and a midline mass if the abscess is in the prevertebral or danger space. Palpation of a fluctuant mass is unreliable and carries a risk of inadvertent rupture. Tenderness on moving the larynx and trachea side to side (tracheal so-called rock sign) is commonly present. A retropharyngeal abscess may also cause pain in the back of the neck or shoulder, precipitated by swallowing. Cold abscesses (caused by tuberculosis) are characterized by insidious onset, chronicity, constitutional symptoms, and a lower fever. Symptoms disproportionate to the findings should prompt further evaluation.

Diagnostic Considerations

Differential Diagnosis

The differential diagnosis includes retropharyngeal tumors, foreign bodies, inflammation, hematoma, aneurysms, hemorrhage, lymphadenopathy, and edema. Other considerations include tendinitis of the longus colli muscle and retropharyngeal thyroid tissue.16

---

Fig. 65.7. Lateral view of the neck showing the relationship of fascia to the prevertebral danger area and retropharyngeal and submandibular spaces.
Consultation with an infectious disease specialist and otolaryngologist is advised when tuberculosis or a fungal infection is suspected as the causative agent.\textsuperscript{15,17}

Neck immobilization may be necessary in patients with vertebral body destruction caused by osteomyelitis or atlantoaxial separation. Atraumatic atlantoaxial separation is caused by damage to the transverse ligament of the atlas from the abscess. These patients may have neurologic symptoms and a widened pretracheal space on plain films or CT or MRI scans. These patients need neurosurgical or orthopedic evaluation and may require fixation.

**Disposition**

Patients with retropharyngeal abscess are admitted to the ICU, and emergent consultation with an otolaryngologist is obtained.

**PARAPHARYNGEAL ABSCESS**

**Principles**

The parapharyngeal space is divided into two compartments by the styloid process. The anterior compartment contains connective tissue, muscle, and lymph nodes. The carotid sheath, which contains the carotid artery, internal jugular vein, vagus nerve, cranial nerves IX through XII, and the sympathetic chain, runs in the posterior compartment. Parapharyngeal abscesses are usually polymicrobial, emanating from an odontogenic or pharyngotonsillar infection. Parapharyngeal space infections can also arise from contiguous spread from deep neck space infections, parotitis, sinusitis, infected neck tumors, infected branchial cleft cysts, suppurative lymphadenitis, chronic otitis with cholesteatoma, mastoiditis, and iatrogenic introduction of organisms during a mandibular nerve block or anesthesia for tonsillectomy, nasal intubation, or dental extraction.

**Clinical Features**

Odynophagia, pain, and swelling of the neck are the most common complaints. A history of an antecedent sore throat may be elicited; torticollis caused by irritation of the sternocleidomastoid muscle is also reported.
The classic physical findings of infection involving the anterior compartment of the parapharyngeal space are medial tonsillar displacement and posterolateral pharyngeal wall bulging. Other findings include fever, trismus, caused by irritation of the muscles of mastication, edema, and swelling at the angle of the mandible, often seen in patients with an anterior parapharyngeal abscess.

Involvement of the posterior space is associated with many of these same signs. If the anterior compartment is spared, however, little or no trismus occurs. Instead, posterior displacement of the tonsillar pillar and retropharyngeal swelling may be present.

Complications of a parapharyngeal abscess include airway obstruction and abscess rupture, with subsequent aspiration, pneumonia, and empyema. Infection can spread to surrounding spaces and into the mediastinum and pericardium. This spread may lead to mediastinitis, mediastinal abscess, pericarditis, myocardial abscess, and/or empyema. Other complications include osteomyelitis of the mandible, cervicothoracic necrotizing fasciitis, parotid abscess, cavernous sinus thrombosis, and meningitis.

Posterior parapharyngeal space infections are particularly dangerous. These may affect the cervical sympathetic chain, carotid artery, or internal jugular vein. Ipsilateral Horner’s syndrome and neuromas of cranial nerves IX through XII may occur. Carotid artery erosion may lead to hemorrhage and the formation of aneurysms. Oral, nasal, and aural warning bleeding is common with carotid artery erosion, with aural bleeding being particularly ominous. Any unexplained bleeding associated with parapharyngeal or other deep neck space infection should be investigated thoroughly. Persistent peritonsillar swelling, despite resolution of the parapharyngeal abscess or a tender unilateral pulsatile mass, may indicate an arterial aneurysm. Aspiration or incision of a carotid artery aneurysm thought to be a parapharyngeal abscess may have disastrous complications.

Involvement of the internal jugular vein may lead to septic thrombosis and Lemierre’s syndrome. This entity, also termed postanginal septicemia, affects primarily young healthy patients and is easily confused with right-sided endocarditis or aspiration pneumonia. The manifestion is one of a pharyngitis that initially improves but is then followed by severe sepsis. It is thought that the pharyngeal infection spreads to the parapharyngeal space and causes septic thrombophlebitis of the jugular vein. Patients usually appear ill and are febrile. Metastatic infections involve primarily the lung and are manifested by bilateral nodular infiltrates, pleural effusion, and pneumothorax. Septic embolization may also lead to arthritis, osteomyelitis, cellulitis and abscesses, meningitis, and a vesiculopustular rash. Positive blood cultures, leukocytosis, and elevated bilirubin levels and liver function tests, with and without hepatomegaly and jaundice, are often present. Albuminuria, hematuria, and elevations in serum creatinine and blood urea nitrogen levels are reported. Septic shock rarely develops, although acute respiratory distress syndrome, transient coagulopathies, and hypotension commonly occur. The most frequent cause of this entity is Fusobacterium (primarily Fusobacterium necrophorum), although Staphylococcus aureus is the most common pathogen in IV drug users. Treatment consists of parenteral antibiotics and incision and drainage of abscesses. Antibiotic regimens include piperacillin-tazobactam, imipenem-cilastatin, high-dose ceftriaxone plus metronidazole, and clindamycin. Jugular vein ligation and resection are necessary in patients with uncontrolled sepsis and respiratory failure caused by repeated septic pulmonary emboli. The value of anticoagulation is unknown.

Diagnostic Considerations

Differential Diagnosis

The differential diagnosis includes infections of other deep spaces of the neck, tumors and metastatic lymph nodes, thyroiditis, branchial cleft cyst, and carotid artery aneurysms.

Diagnostic Strategies

Ultrasoundography, CT, and MRI are more useful than lateral radiography in diagnosing parapharyngeal abscess and its complications (Fig. 65.10). Angiography, Doppler flow studies, and magnetic resonance angiography may also be helpful in evaluating vascular complications.

Management

Treatment includes high-dose IV antibiotics and consultation with an otolaryngologist for surgical drainage. Appropriate antibiotic regimens are those used for retropharyngeal abscess. IV antibiotics alone will cure parapharyngeal space infections in patients without abscess. The successful resolution of parapharyngeal abscesses with IV antibiotics and needle aspiration has been reported.

Disposition

Patients with parapharyngeal infections require emergent consultation with an otolaryngologist and admission to the ICU. These patients may require emergent surgical intervention.

RHINOSINUSITIS

Principles

Because sinusitis usually involves the nasal cavity, the term rhinosinusitis is preferred. These terms will be used interchangeably in this section.

The paranasal sinuses—frontal, maxillary, ethmoid, and sphenoid—are named for the facial bones with which they are associated. Pneumatization may involve other bones but represents extension from the main sinus. The maxillary, anterior ethmoid, and frontal sinuses drain into the medial meatus, located between the inferior and middle nasal turbinates. This area is termed the ostiomeatal complex and is the focal point of sinus disease. The posterior ethmoid sinus drains into the superior meatus and sphenoid sinus just above the superior turbinate.

A healthy sinus is sterile, depends on a patent ostium with free air exchange, and is reliant on appropriate mucus drainage. Many different processes can result in ostial obstruction and

Fig. 65.10. CT scan demonstrating a left-sided parapharyngeal abscess.
rhinosinusitis, but the most common are viral upper respiratory tract infections and allergic rhinitis. Ciliary abnormality or immobility also inhibits drainage, resulting in sinusitis. Bacteria are introduced into the sinus by coughing and vigorous nose blowing, leading to increased inflammation, decreased oxygen tension in the sinus, and bacterial overgrowth. Other factors predisposing to rhinosinusitis include immunocompromise, nasal septal deviation and other structural abnormalities, nasal polyps, tumors, trauma and fractures, rhinitis medicamentosa, rhinitis secondary to toxic mucosal exposure, barotrauma, foreign bodies, nasal cocaine abuse, and instrumentation, including nasogastric and nasotracheal intubation.19

Sinusitis can be classified into acute viral, acute bacterial, chronic, and recurrent acute variations. Approximately 90% of patients with colds have an element of the acute viral form. Acute viral sinusitis may lead to the development of the acute bacterial variety. *Streptococcus pneumoniae*, nontypable *H. influenzae*, and *Moraxella catarrhalis* are the primary pathogens responsible for acute bacterial and recurrent acute sinusitis. *Pseudomonas aeruginosa* is associated with sinusitis in the setting of HIV infection and cystic fibrosis. Anaerobic bacteria, streptococcal species, and *S. aureus* are more prominent causes of chronic sinusitis. Fungi also have a role in chronic sinusitis. *Rhizopus, Aspergillus, Candida, Histoplasma, Blastomyces, Coccioidiodes*, and *Cryptococcus* spp., as well as other fungi, may cause sinusitis, primarily in immunocompromised hosts. It is important to distinguish infectious from allergic sinusitis. Allergic sinusitis is associated with sneezing, itchy eyes, allergen exposure, and previous episodes.19

**Clinical Features**

Frontal sinusitis can cause severe headache localized to the forehead and orbit. Sphenoid sinusitis may cause vague headaches and focal pain almost anywhere in the head. Maxillary sinusitis may be seen with pain over the zygoma, in the canine or bicuspid teeth, or periorbitally. Ethmoid sinusitis can cause medial canthal pain and periorbital or temporal headaches.19

The cardinal findings of acute rhinosinusitis are mucopurulent nasal discharge, nasal obstruction or congestion, and facial pain, fullness, or pressure lasting less than 4 weeks. Other symptoms and signs include postnasal drip (which may lead to coughing), pressure over the involved sinus, malaise, hyposmia, anosmia, fever, maxillary dental pain, and ear fullness or pressure. Acute sinusitis typically progresses over a period of 7 to 10 days and resolves spontaneously. During the first 3 to 5 days of illness, it may be difficult to differentiate acute viral from acute bacterial sinusitis; antibiotics are not indicated in this phase because most cases are viral and will resolve without treatment. Bacterial sinusitis is more likely, and antibiotics are warranted when symptoms persist beyond 10 days, or with severe onset of disease (fever > 39°C [102.2°F] with severe facial pain or purulent nasal discharge) for at least 3 or 4 consecutive days. Bacterial origin also is suggested by so-called double sickening, which refers to patients who improve initially, only to have worsening sinus congestion and discomfort. In addition, the diagnosis of sinusitis is made in the pediatric population when a child with an upper respiratory infection presents with persistent illness (daytime cough or nasal discharge) longer than 10 days without improvement, a worsening course (worsening or new nasal discharge, daytime cough, or fever after initial improvement), or severe onset of symptoms (concurrent fever and purulent nasal discharge for at least 3 days).19,20

Chronic sinusitis is slow in onset, prolonged in duration (>12 weeks), and recurrent. Symptoms can be nonspecific but are generally similar to those of acute disease. Symptoms of chronic disease may include chronic cough, fetid breath, laryngitis, bronchitis, and worsening asthma. Recurrent acute sinusitis is diagnosed when four or more episodes of acute bacterial infection, without its symptoms or signs between episodes, occur annually. The presentation and treatment of recurrent acute disease is similar to that for acute bacterial sinusitis.19 Invasive fungal sinusitis (mucormycosis) is an aggressive opportunistic rhinocerebral infection that affects immunocompromised hosts. Mucormycosis (*Rhizopus*) is generally associated with fever, localized nasal pain, and cloudy rhinorrhea. On examination, the affected tissue (usually the turbinates) appears gray, friable, anesthetic, and nonbleeding because of infarction caused by mucormycotic angioinvasion. In advanced cases, the affected tissues are necrotic and black, and the infection spreads beyond the sinus.19

**Diagnostic Considerations**

**Differential Diagnosis**

Rhinitis can be differentiated from sinusitis by the increased response of nasal obstruction to treatment, clear nasal discharge, and absence of pain or fever. Rhinitis does not lead to ostial obstruction, and patients do not complain of facial pain. Malignancy, tension headache, vascular headache, foreign body, dental disease, brain abscess, epidermal abscess, meningitis, and subdural empyema may also manifest in a manner similar to that of sinusitis.

**Diagnostic Testing**

Physical examination is best performed after the application of a topical decongestant. Mucosal erythema and edema are usually present. Purulent discharge from the nasal meatus may be observed if the sinus ostia are not completely obstructed. In the setting of acute sinusitis, nasal and nasopharyngeal cultures do not differentiate between acute viral and acute bacterial infections and are not indicated. Culture and biopsy are indicated in suggested chronic, recurrent acute, and fungal sinusitis.19

For suspected acute sinusitis, routine radiographic examination is not recommended and should be limited to the diagnosis of chronic or recurrent acute sinusitis, cases of questionable diagnoses, patients with unresponsive disease, or investigation of complications. Axial and coronal CT is the imaging modality of choice. CT findings suggestive of sinusitis include air-fluid levels, sinus opacification, sinus wall displacement, and mucosal thickening (Fig. 65.11). CT is sensitive, although not specific. Incidental sinus mucosal thickening is seen in 40% of asymptomatic patients, and abnormal CT findings can also be noted in just 50% of patients with seasonal allergies. CT with IV contrast or MRI may be required to evaluate complications of rhinosinusitis and are helpful in determining alternative diagnoses. In children, CT or MRI with IV contrast should be performed if there is suspicion of orbital or central nervous system complications. Sinus endoscopy is an optional diagnostic modality for the evaluation of sinusitis.19,20

**Management**

Most cases of acute sinusitis are self-limited and resolve spontaneously; therefore, management should focus on symptomatic treatment and patient education. The goal of symptomatic treatment should be to reduce patient discomfort; it includes appropriate pain management and local decongestant therapy. When allergic symptoms are prominent or the patient has a history of allergic rhinosinusitis, antihistamines, such as loratadine, 10 mg daily, are helpful, but antihistamines otherwise are of no value.19

Decongestant therapy, available in topical and systemic preparations, can be used to reduce tissue edema, facilitate drainage, and maintain patency of the sinus ostia.19 Topical agents provide more relief than systemic decongestants. Longer acting agents,
such as 0.05% oxymetazoline hydrochloride, are easy to use and highly effective. Topical agents should be used for up to 5 days because extended use results in rebound vasodilation and nasal obstruction, a condition termed rhinitis medicamentosa. Systemic oral adrenergic agonists (eg, phenylpropanolamine, pseudoephedrine) offer no advantage over topical agents and have significant systemic effects, so they should not be used unless the patient is unwilling to use topical decongestants. They should not be used in patients with poorly controlled hypertension or patients who are taking tricyclic antidepressants, monoamine oxidase inhibitors, or nonselective β-adrenergic blockers." Topical and systemic steroids offer modest benefit when used in conjunction with antibiotics for the treatment of bacterial sinusitis. Topical but not systemic steroids are indicated for chronic and allergic sinusitis. Systemic steroids may be indicated in allergic and chronic sinusitis with nasal polyps.

Sinus self-irrigation with a Neti pot or powered commercial irrigator can be helpful for patients with chronic low-grade symptoms or frequently recurring acute episodes. Saline nasal irrigation is beneficial for the treatment of acute bacterial, recurrent acute, and chronic sinusitis and even may be efficacious for the prevention of sinusitis. Hypertonic saline preparations have superior antiinflammatory properties and may be more effective than normal saline.

Antibiotic therapy should be initiated when the diagnosis of acute bacterial sinusitis is established. In children, those with severe onset or worsening symptoms should be treated with antibiotics. Children with persistent symptoms and one of the following should also be treated with antibiotics: (1) antibiotic therapy in the last 4 weeks; (2) concurrent bacterial infections; (3) actual or suspected complications of sinusitis; or (4) underlying conditions (eg, asthma, cystic fibrosis, anatomic abnormalities of the upper respiratory tract, immunodeficiency). Children with persistent stable symptoms may be managed with antibiotics or an additional short (usually up to 3-day) period of observation because there is low risk for complications in these patients, and the symptoms may resolve on their own. Patients who do not improve within 72 hours should be treated with antibiotics. The choice of antibiotics should consider β-lactamase production and multidrug-resistant pneumococci. Amoxicillin-clavulanate for 5 to 7 days in adults and 10 days in children is the first-line agent for uncomplicated bacterial sinusitis. High-dose amoxicillin-clavulanate is recommended as empirical treatment for patients from areas in which there are high endemic rates of invasive S. pneumoniae, severe infections, and those at risk for suppurative complications, such as patients who have recently been hospitalized, used antibiotics within the past 4 to 6 weeks, are older than 65 years, or are immunocompromised. Penicillin-allergic patients may be treated with levofoxacin, or doxycycline may be used in adults and, in children, a combination of clindamycin plus cephalaxine or cefpodoxime may be used in those with non–type I penicillin allergy. Children who are vomiting, unable to tolerate oral medications, or are at risk for nonadherence to oral therapy can be treated with an initial dose of 50 mg/kg of ceftriaxone (IV or IM) until they are able to tolerate oral antibiotics. Trimethoprim-sulfamethoxazole, macrolides, and second- and third-generation cephalexin antibiotics are no longer recommended as empirical therapy due to bacterial resistance.

Failure of symptoms to resolve after 3 to 5 days of antibiotic therapy, or patients who worsen after 48 to 72 hours of empirical antibiotics, necessitate reassessment to confirm the diagnosis of acute bacterial sinusitis, a change to an alternate antibiotic regimen for 5 to 10 days, and referral to an otolaryngologist. Appropriate management for patients with mild to moderate disease includes amoxicillin-clavulanate, cefpodoxime, and cefdinir. Patients with severe disease should be treated with a respiratory fluoroquinolone. Treatment of life-threatening complications requires consultation and high-dose IV antibiotics. Patients with chronic sinusitis should be referred to an otolaryngologist. Antibiotics may be helpful in the setting of chronic sinusitis and should be effective against anaerobic and β-lactamase–producing bacteria. Amoxicillin-clavulanate or clindamycin for 3 to 10 weeks may be used. Antifungals may be beneficial in the treatment of chronic sinusitis.

**Disposition**

Most patients with rhinosinusitis can be treated on an outpatient basis. Frontal or sphenoid sinusitis with air-fluid levels may necessitate hospitalization. A previously healthy, nontoxic patient with good home support can be treated as an outpatient but should return immediately for any symptoms or signs of complications, including severe headache, neurologic changes, and visual changes. Patients who appear toxic, are immunocompromised, or have poor home resources require hospital admission and IV antibiotics.
Most cases of pharyngitis have a viral cause. CENTOR clinical criteria in conjunction with RST can be used to determine the likelihood of GAS pharyngitis.

Rheumatic fever is rare in developed countries, where it may occur in epidemics.

Although rare, local (airway) and systemic life-threatening complications of bacterial pharyngitis do occur.

A severe sore throat with surprisingly minimal findings on examination of the oropharynx suggests serious soft tissue infection, such as epiglottitis or retropharyngeal abscess.

Deep space cellulitis is difficult to differentiate from deep space abscess and may require needle aspiration after CT or MRI.

Patients with upper airway infections should be kept in a position of comfort. Patients with epiglottitis prefer the classic sniffing position, whereas those with a retropharyngeal abscess prefer to lie supine.

Posterior to the retropharyngeal space lies the danger space, which extends from the base of the skull to the superior mediastinum at about the level of T2.

Resolving pharyngitis followed by severe sepsis, right-sided endocarditis, or aspiration pneumonia should suggest septic thrombosis of the internal jugular vein and Lemierre’s syndrome.

Imaging is rarely indicated in the setting of sinusitis and should be reserved for complex presentations or if there is a suspicion of complications.

In children with persistent and stable sinusitis, a 3-day period of observation prior to the initiation of antibiotics is effective.

CHAPTER 65: Upper Respiratory Tract Infections

65.1. Which of the following associations regarding pharyngitis is true?
   A. Appears clinically well—diphtheria
   B. Cervical adenopathy—influenza
   C. Conjunctivitis—coryzae with virus
   D. No pharyngeal exudates—infectious mononucleosis
   E. Pharyngeal exudates—adenovirus

   Answer: E. Adenovirus often mimics streptococcal pharyngitis regarding the appearance of the exudate. It is also associated with conjunctivitis, rather than coryzae with virus, which is associated with hand-foot-and-mouth disease. Influenza rarely shows cervical adenopathy or pharyngeal exudates. Infectious mononucleosis typically exhibits a tonsillar exudate or membrane. Diphtheria cases are usually toxic-appearing.

65.2. A 9-year-old boy presents with fever, neck tenderness, and painful swallowing. The physical examination reveals a well-developed boy in no distress with oral temperature, 39.2°C (102.6°F), heart rate, 125 beats/min, respiratory rate, 22 breaths/min, blood pressure, 100/60 mm Hg, and O2 saturation, 99%. Examination reveals whitish bilateral tonsillar exudates, tenderness anterior cervical adenopathy, clear lungs, and normal tympanic membranes. Appropriate treatment measures include which of the following?
   A. Admission for intravenous antibiotics
   B. Amoxicillin daily for 10 days
   C. Discussion with the family that antibiotic treatment prevents rheumatic fever but does not shorten illness duration
   D. Symptomatic treatment only
   E. Symptomatic treatment, throat culture, and return visit within 3 to 4 days for culture review and antibiotics as indicated

   Answer: B. A 10-day course of penicillin or cephalosporin is the treatment of choice. The antibiotic regimen of choice for adults with group A beta-hemolytic Streptococcus (GAS) pharyngitis is a single intramuscular injection of 1.2 million units of benzathine penicillin. Culture and follow-up visits are acceptable practice but time-consuming and expensive. Symptomatic treatment is only indicated when GAS has been ruled out. Antibiotic treatment prevents rheumatic fever and modestly shortens illness duration.

65.3. A 10-year-old boy, who recently immigrated to the United States from Honduras, complains of 3 days of sore throat, fever, and trouble swallowing. Examination reveals a healthy boy in mild distress with a grayish membrane covering the soft palate, pharynx, and uvula. The airway is patent. The child is slightly hoarse. He has bilateral tender anterior cervical adenopathy; his lungs are clear. Vital signs are temperature, 102.5°F (39°C) oral, heart rate, 130 beats/min, blood pressure, 105/65 mm Hg, respiratory rate, 28 breaths/min, and O2 saturation 100%. Which of the following treatments is most appropriate?
   A. Antitoxin
   B. High-dose corticosteroids
   C. High-dose intravenous penicillin
   D. Nebulized racemic epinephrine treatments
   E. Urgent endotracheal intubation

   Answer: A. This is diphtheria. Urgent antitoxin is necessary. The toxin may produce airway collapse, vocal cord necrosis, neuritis, and carditis. Antibiotics eradicate only the carrier state. Corticosteroids do not affect the toxin-induced damage. The status of the child does not warrant emergent endotracheal intubation because his hoarseness is only mild and he has a patent airway, although he must be closely monitored.

65.4. A 14-year-old girl returns to the ED 1 week after completing a 10-day course of penicillin for rapid strep test–confirmed GAS pharyngitis. She reports identical symptoms return 1 week after completion of her antibiotics. Examination is again consistent with an exudative pharyngitis. Which of the following is indicated?
   A. Admission for intravenous antibiotics
   B. Cephalexin, 10-day course
   C. Counseling the family that this is likely infectious mononucleosis and symptomatic treatment is warranted
   D. Intramuscular benzathine penicillin, 1.2 million units
   E. Repeat rapid strep testing

   Answer: D. Such patients may have been noncompliant or reinfected by asymptomatic contacts. Throat culture, surveillance of contacts, and intramuscular penicillin are indicated.
**CHAPTER 66**

**Pneumonia**

Gregory J. Moran | Matthew A. Waxman

---

**PRINCIPLES**

**Background and Importance**

Pneumonia is the leading infectious cause of death worldwide, with over 3.1 million deaths annually. In the United States, there are over 4 million adult cases of community-acquired pneumonia (CAP) annually. The economic burden associated with CAP annually in the United States is over $17 billion dollars. Most cases of CAP are managed in the outpatient setting, and the mortality is low (~1%). Pneumonia necessitating hospitalization is associated with a mortality rate as high as 20%. Pneumonia remains challenging because of an expanding spectrum of pathogens, changing antibiotic resistance patterns, continued introduction of newer antimicrobial agents, and increasing emphasis on cost-effectiveness and outpatient management.

The epidemiology of CAP is changing. As the percentage of the population older than 65 years continues to increase, the incidence of pneumonia is expected to increase. An increasing number of patients are taking immunosuppressive drugs related to the treatment of malignancy, transplantation, or autoimmune disease, resulting in more cases of pneumonia from opportunistic pathogens. *Streptococcus pneumoniae* is the most frequently identified pathogen and is also associated with increasing antimicrobial resistance. In addition, the threat exists of respiratory infections caused by biologic terrorism or newly recognized pathogens such as Middle East respiratory syndrome that have the potential to spread globally through international travel.

**Anatomy and Physiology**

Despite the constant presence of potential pathogens in the respiratory tract, the lungs are remarkably resistant to infection. The alveolar surface of the lungs covers an area of approximately 140 m², about 10,000 L of air passes through the respiratory tract each day, and typical ambient air can contain hundreds to thousands of microorganisms per cubic meter. Although the cough and laryngeal reflexes prevent most large particulate matter from entering the lower respiratory tract, aspiration of oropharyngeal contents may be a common occurrence during normal sleep. Despite these hazards, the lower airway tract is a virtually sterile environment.

**Pathophysiology**

The development of clinical pneumonia requires a defect in host defenses, presence of a particularly virulent organism, or introduction of a large inoculum of organisms. Pneumonia commonly results from microaspiration of upper respiratory pathogens into the sterile lower respiratory tract. If the challenge of invading organisms overwhelms host defenses, microbial proliferation leads to inflammation, an immune response, and clinical pneumonia. If host defenses are weak, a minimal challenge may lead to the development of pneumonia. The challenge with pneumonia is identifying the causative agent rather than making the diagnosis in general. It is unlikely that a specific pathogen can be identified in the emergency department (ED), but a careful history, including foreign travel, recent antibiotic use, and exposure to the health care system, can help inform empirical therapy. Empirical therapy should be chosen with activity against the spectrum of likely pathogens based on the patient’s overall clinical presentation.

There is difficulty in determining the specific cause of pneumonia because advanced microbiologic and serologic testing is generally not available during an ED evaluation. In CAP, a microbial cause cannot be determined in more than 50% of cases, even after a thorough inpatient investigation. Among hospitalized adults in whom a pathogen can be identified, organisms such as *S. pneumoniae* and *Haemophilus influenzae*, referred to as typical pathogens, account for approximately 50% of cases. *Legionella*, *Mycoplasma*, and *Chlamydia* (previously known as *Chlamydia* spp., referred to as atypical pathogens, are also common.

Testing for common viral agents reveals a viral cause in approximately 18% of cases, with influenza and parainfluenza viruses being the most common.

Among adults requiring intensive care unit (ICU) admission, *S. pneumoniae* is the most common pathogen, with even higher prevalence among fatal cases. *Legionella* spp., *Staphylococcus aureus* (including methicillin-resistant *S. aureus* [MRSA]), and aerobic gram-negative bacilli also appear to be relatively more common among adults with severe CAP. Atypical organisms, such as *Mycoplasma* species or viruses, account for a relatively higher proportion of pneumonia in patients who have milder illness amenable to outpatient therapy.

Atypical organisms can also occur with significant frequency in patients with severe illness requiring hospitalization, particularly because of *Legionella* infection. Coinfection, such as with *Chlamydia pneumoniae* and *S. pneumoniae*, is also well recognized.

*S. pneumoniae* is a gram-positive coccus that is the most common cause of CAP in adults requiring hospitalization. It colonizes the nasopharynx in 40% of healthy adults. Although this organism can cause pneumonia in healthy people, patients with a history of diabetes, cardiovascular disease, alcoholism, sickle cell disease, splenectomy, and malignancy or other immunosuppressive illness are at increased risk. A vaccine containing the 23 capsular polysaccharides of pneumococcal types most commonly associated with pneumonia reduces the likelihood of serious pneumococcal infection. It is recommended for adults at increased risk because of underlying illness or age older than 65 years.

Despite this recommendation, many ED patients have not received the pneumococcal vaccine, and vaccinating eligible patients in this setting seems to be feasible and effective. A 13-valent protein-conjugate pneumococcal vaccine effectively reduces invasive pneumococcal disease and pneumonia in infants and young children. Although underused in the adult population, the vaccine has resulted in a marked decrease in the incidence of pneumococcal pneumonia.

*H. influenzae*, the second most frequently isolated organism in CAP among adults, is a pleomorphic gram-negative rod. It is
a common pathogen in adults with chronic obstructive pulmonary disease (COPD), alcoholism, malnutrition, malignancy, or diabetes.

*S. aureus* may be emerging as a more common cause of CAP and has been found more frequently than *H. influenzae* in some recent series. Community-associated strains of methicillin-resistant *S. aureus* (CA-MRSA) are uncommon in CAP but are more likely to cause severe disease. Often associated with influenza, staphylococcal pneumonias are often necrotizing, with cavitation and pneumatocele formation. Intravenous (IV) drug users may develop hematogenous spread of *S. aureus* that involves both lungs, with multiple small infiltrates or abscesses (eg, tricuspid endocarditis resulting in septic pulmonary emboli).

*Klebsiella pneumoniae* is a gram-negative rod that rarely causes disease in a normal host and accounts for a small percentage of cases of CAP. It may cause severe pneumonia in debilitated patients with alcoholism, diabetes, or other chronic illness. There is a high incidence of antibiotic resistance because the organism is often hospital-acquired.

*Mycoplasma pneumoniae* is one of the most common causes of CAP in previously healthy patients younger than age 40 years. Another important organism in CAP is *C. pneumoniae*, an intra-cellular parasite that is transmitted between humans by respiratory secretions or aerosols. Seroprevalence studies have indicated that virtually everyone is infected with *C. pneumoniae* at some time and that reinfection is common, particularly in older adults. It accounts for at least 10% of CAP cases treated as outpatients, although this is an underestimate owing to difficulty in diagnosing infection with this organism.

At least 30 species of *Legionella* have been isolated since the 1976 convention-related outbreak in Philadelphia, from which the organism derives its name. At least 19 are known human pathogens. *Legionella* is an intracellular organism that lives in aquatic environments. There is no person-to-person transmission. Although it is implicated in point outbreaks related to cooling towers and similar aquatic sources, the organism also lives in ordinary tap water and is underdiagnosed as a cause of CAP. *Legionella* prevalence seems to vary greatly by region.

Lower respiratory infections caused by anaerobic organisms generally result from the aspiration of oropharyngeal contents with large amounts of bacteria. These infections are typically polymicrobial, including *Peptostreptococcus*, *Bacteroides*, *Pseudomonas*, and *Prevotella* spp. Presentation is often subacute or chronic and may be difficult to distinguish clinically from other causes of pneumonia. Clinical factors that suggest an anaerobic infection include risk factors for aspiration, such as central nervous system depression or swallowing dysfunction, severe periodontal disease, fetid sputum, and presence of a pulmonary abscess or empyema.

Viral pneumonias are common in infants and young children and are recognized as an important cause of pneumonia in adults. Respiratory syncytial virus and parainfluenza viruses are the most common causes of pneumonia in infants and small children, occurring mostly during autumn and winter. Influenza viruses are the most common cause of viral pneumonia in adults. Winter influenza outbreaks, usually of influenza type A, may cause up to 40,000 deaths annually in the United States. More than 90% occur in people aged 65 years or older. Metapneumovirus is a paramyxovirus that is an important cause of viral pneumonia in children and adults.

Fungal infections caused by organisms such as *Histoplasma capsulatum*, *Blastomyces dermatitidis*, and *Coccidioides immitis* commonly manifest as pulmonary disease. These organisms are present in the soil in various US geographic areas—*H. capsulatum* in the Mississippi and Ohio River valleys, *C. immitis* in desert areas of the Southwest, and *B. dermatitidis* in a poorly defined area extending beyond that of *H. capsulatum*. These infections should be considered in people in appropriate geographic areas, especially in those who are near activities that disturb the soil, such as construction or dirt bike riding, and in patients who do not respond to antibacterial antibiotics. The clinical presentation varies from an acute or chronic pneumonia to asymptomatic granulomas and hilar adenopathy.

*Pneumocystis* pneumonia (PCP) occurs in immunocompromised hosts, principally those with acquired immunodeficiency syndrome (AIDS) or malignancy. *Pneumocystis jiroveci* (previously known as *Pneumocystis carinii*) is one of the most common infections leading to a diagnosis of HIV infection and AIDS. Patients with pulmonary complaints should be questioned about HIV risk factors, and emergency clinicians should search for signs of HIV-related immunosuppression, such as weight loss, lymphadenopathy, and oral thrush. PCP typically manifests subacutely with fatigue, exertional dyspnea, nonproductive cough, pleuritic chest pain, and fever.

*Mycobacterium tuberculosis* is a slow-growing bacterium transmitted between people by droplet nuclei produced from coughing and sneezing. *M. tuberculosis* survives within macrophages as a facultative intracellular parasite and may remain dormant in the body for many years. Active tuberculosis (TB) develops within 2 years of infection in approximately 5% of patients, and another 5% develop reactivation disease at some later time. Reactivation is more likely to occur in people with impaired cell-mediated immunity, such as patients with diabetes, renal failure, immunosuppressive therapy, malnutrition, or AIDS. Approximately one-third of the world’s population is infected with *M. tuberculosis*; about 9 million new cases of active disease develop annually, resulting in 1.5 million deaths worldwide. Approximately 10,000 patients/year in the United States develop tuberculosis. Multidrug-resistant strains of *M. tuberculosis* have been found in increasing numbers, especially among patients with HIV and in immigrants from Southeast Asia.

**Clinical Features**

The ED evaluation should focus on establishing the diagnosis of pneumonia and determining the presence of epidemiologic and clinical features that would influence decisions regarding hospitalization and antibiotics. Key components of the history include character of symptoms, setting in which the pneumonia is acquired, recent contact with the health care system, geographic or animal exposures, and host factors that predispose to certain types of infections and are associated with outcome.

Pneumonia generally manifests as a cough productive of purulent sputum, shortness of breath, and fever. In most healthy older children and adults, the diagnosis can be reasonably excluded on the basis of history and physical examination, with suspected cases confirmed by chest radiography. The absence of any abnormalities in vital signs or chest auscultation substantially reduces the likelihood of pneumonia as demonstrated by radiography. No single isolated clinical finding, however, is highly reliable in establishing or excluding a diagnosis of pneumonia.

Older or debilitated patients with pneumonia often have nonspecific complaints, such as acute confusion or a deterioration of baseline function, without classic symptoms. Similarly, older patients may not present with a well-defined infiltrate on radiography. Older patients are more likely to have advanced illness at the time of presentation and may have sepsis in the absence of a previous syndrome suggestive of pneumonia. Occasionally, patients with lower lobe pneumonia have abdominal or back pain as a presenting symptom.

Classic teaching divides pneumonia based on clinical patterns into typical pneumonia caused by pyogenic bacteria, such as *S. pneumoniae* or *H. influenzae*, and atypical pneumonia caused by organisms such as *Mycoplasma* and *Chlamydia spp.* This
Classic teaching is artificial, and a clear differentiation between these two types of pneumonia on clinical grounds alone is impossible. Certain clinical factors may be suggestive of atypical organisms. Factors studied prospectively and found not to help differentiate atypical pneumonias from those with pyogenic bacterial causes include gradual onset, viral prodrome, absence of rigors, nonproductive cough, lower degree of fever, absence of pleurisy or consolidation, normal leukocyte count, and an ill-defined infiltrate on a chest radiograph. Although it is impossible to determine the specific cause of pneumonia with a high degree of certainty without the results of microbiologic or serologic tests, certain clinical factors suggest that a specific pathogen should be considered.

Clinical factors suggesting pneumococcal pneumonia include the abrupt onset of a single shaking chill, followed by fever, cough productive of rust-colored sputum, and pleuritic chest pain. Patients with a history of asplenia, sickle cell disease, AIDS, multiple myeloma, or agammaglobulinemia are at increased risk of pneumococcal bacteremia and sepsis, with high mortality rates. Adults with chronic lung disease who develop pneumonia caused by \textit{H. influenzae} typically demonstrate an insidious worsening of baseline cough and sputum production, and bacteremia is rare. \textit{K. pneumoniae} may cause severe pneumonia in older or debilitated patients with so-called currant jelly sputum from the necrotizing nature of the infection. Abscess formation, empyema, and bacteremia are common with this organism, and mortality is high.

Atypical pneumonia is caused by organisms such as \textit{M. pneumoniae}, \textit{C. pneumoniae}, viruses, \textit{Legionella} spp., or rickettsiae such as \textit{Coxiella burnetii}. Mycoplasmal infection usually begins as a flulike illness with headache, malaise, fever, and nonproductive cough. Skin lesions, including maculopapular, vesicular, urticarial, or erythema multiforme–type rashes, are common, especially in younger patients. Although bullous myringitis is described as a classic finding, it is not specific for mycoplasmal infection and is seldom encountered. Patients generally do not have a toxic appearance, and most can be treated on an outpatient basis. Although mucopurulent sputum generally indicates the presence of pyogenic bacterial pneumonia or bronchitis, it may also be present with mycoplasmal or viral pneumonia. Viral pneumonia in adults is often preceded by symptoms of upper respiratory infection, such as rhinitis or sore throat. Most \textit{C. pneumoniae} infections in young adults cause a minor, self-limited, upper respiratory illness that is subacute in onset. This organism is also associated with bronchitis, wheezing, sinusitis, and pharyngitis. Development of radiographically evident pneumonia is more common in older adults with \textit{C. pneumoniae}. Some patients with \textit{Legionella} infection have a mild, self-limited atypical pneumonia presentation. Older patients, smokers, and those with chronic disease or immunosuppression are more prone to develop the more acute and severe systemic illness of Legionnaires’ disease. Gastrointestinal symptoms, such as diarrhea and abdominal cramping, confusion, and muscle aches are sometimes prominent.

In addition to age, the presence of underlying illness, and presenting symptoms, the setting of acquisition of pneumonia may provide clues to likely causes. CAP that occurs in otherwise healthy individuals is likely to be caused by viruses, \textit{Mycoplasma} spp., or \textit{S. pneumoniae}. \textit{S. aureus}, including MRSA, can cause severe pneumonia associated with influenza. Recently hospitalized and long-term care patients may develop pneumonia from agents that are uncommon in CAP, such as Enterobacteriaceae, \textit{Pseudomonas aeruginosa}, and \textit{S. aureus}. Healthy patients in an institutional setting, such as a dormitory or military barracks, are likely to have pneumonia caused by \textit{Mycoplasma} spp. or viruses.

Patients with underlying lung disease, especially COPD, constitute an important group likely to develop pneumonia. The lower respiratory tract of these patients is commonly colonized with organisms such as \textit{S. pneumoniae}, \textit{H. influenzae}, and \textit{Moraxella catarrhalis}. Cystic fibrosis patients are prone to pneumonia caused by \textit{P. aeruginosa} or \textit{S. aureus}. Defective mucociliary clearance in both these groups makes them highly susceptible to repeated episodes of pneumonia.

Patients with immunosuppression as a result of hematoologic malignancy, patients receiving chemotherapy for malignancy, and transplant recipients are prone to pulmonary infections with a wide variety of organisms. In addition to the usual pathogens, these patients may develop pneumonia secondary to viruses such as cytomegalovirus (CMV), varicella, or herpes simplex virus. They are also more likely to develop pneumonia caused by aerobic gram-negative bacilli, \textit{Aspergillus} and geographic fungi, and \textit{P. jiroveci}.

Although the use of highly active antiretroviral therapy (HAART) has decreased the incidence of opportunistic infections among HIV-infected patients, individuals who are not under regular care often come to the ED. In addition to \textit{P. jiroveci}, there is also an increased incidence of \textit{M. tuberculosis} and common bacterial pathogens such as \textit{S. pneumoniae}. Bacterial pneumonia remains the most common pneumonia in HIV-infected patients. Other less common causes of pneumonia in HIV-infected patients include \textit{Mycobacterium avium} complex, \textit{CMV}, aerobic gram-negative bacilli, and \textit{Cryptococcus neoformans}. PCP usually has a subacute presentation characterized by nonproductive cough, exertional dyspnea, and weight loss. Hypoxemia, hypocapnia, and an increased arterial-alveolar oxygenation gradient are usually present. A clinical clue suggesting PCP pneumonia in the ED is a significantly decreased oxygen saturation with ambulation in the setting of HIV disease or risk factors.

The potential for opportunistic pulmonary infection can be predicted by a recent absolute CD4 lymphocyte count less than 200/mm³. This count is often known by patients with recognized HIV infection or may be surmised by a peripheral total lymphocyte count less than 1000/mm³. In patients who do not know their HIV status, the presence of findings such as weight loss, hairy leukoplaikia, and oral candidiasis strongly suggests immunosuppression.

Patients in nursing homes and extended-care facilities are at increased risk for infection with resistant organisms such as \textit{P. aeruginosa}, \textit{K. pneumoniae} (including strains producing extended-spectrum \textit{β}-lactamasas), \textit{Acinetobacter} spp., and hospital-associated strains of MRSA. In 2005, the American Thoracic Society/Infectious Disease Society of America (ATS/IDSA) issued guidelines for the management of patients who may be at risk for multidrug resistance based on recent exposure to the health care system. See Box 66.1 for definitions of hospital-acquired, ventilator-associated, and health care–associated pneumonia (HCAP). An important part of the initial evaluation of the patient with pneumonia is a careful history and review of the medical record for recent exposure to the health care system. HCAP is associated with a greater likelihood of resistant pathogens such as \textit{Pseudomonas} and MRSA, and mortality is higher than that for CAP.

**Diagnostic Considerations**

**Differential Diagnoses**

Differentiation between upper and lower respiratory tract infections may be difficult. A chest radiograph helps differentiate between upper respiratory tract infection or bronchitis and pneumonia.

Many noninfectious conditions may result in inflammatory lung processes, including exposure to mineral dusts (eg, silicosis), chemical fumes (eg, chlorine and ammonia), toxic drugs (eg, bleomycin), radiation, thermal injury, or oxygen toxicity. Immunologic disease (eg, sarcoidosis, Goodpasture’s syndrome, and
may initially have coughing or shortness of breath or may appear well initially and then develop respiratory dysfunction during the next several hours.

Acute aspiration of acidic fluid into the lungs causes a chemical pneumonitis. This may produce fever, leukocytosis, purulent sputum, and radiographic infiltrates that mimic those of bacterial pneumonia. Although some patients go on to develop bacterial pneumonia, prophylactic administration of antibiotics is controversial. Antibiotics should be initiated if the patient develops signs of bacterial pneumonia, including new fever, expanding infiltrate appearing more than 36 hours after aspiration, or unexplained deterioration.

Diagnostic Testing

Although many chest radiographs are obtained unnecessarily for patients with upper respiratory tract infections or bronchitis, it is difficult to identify a set of specific criteria to direct test ordering that is better than the clinical judgment of an experienced physician. A routine chest radiograph for all patients with cough is not necessary. Computed tomography (CT) of the chest is more sensitive than plain radiography for detecting the presence of pulmonary consolidation, although the natural history of CT-positive, plain radiograph-negative pneumonia is not clear. CT of the chest should be considered in patients such as older adults or those with significant comorbidities, for whom identification of a subtle infiltrate would change management. Young healthy adults with a presumptive diagnosis of pneumonia who will be treated as outpatients may have a chest radiograph deferred unless there is a suspicion of immunocompromise or other unusual features of disease. A chest radiograph should be obtained subsequently if there is a poor initial response to treatment. Routine performance of chest radiography for patients with exacerbation of chronic bronchitis or COPD is of low yield and may be limited to patients with other signs of infection or congestive heart failure.

Although the causative agent cannot be determined solely by the results of chest radiography, certain radiographic patterns may suggest the possibility of specific pathogens. In pyogenic bacterial pneumonias, radiographs usually show an area of segmental or subsegmental infiltration and air bronchograms (Fig. 66.1). Lobar

consolidation is present in a few cases of bacterial pneumonia, often caused by pneumococci or \textit{Klebsiella}. A dense lobar infiltrate with a bulging fissure appearance on a chest radiograph is often described with pneumonia caused by \textit{Klebsiella}, but this finding is nonspecific, and most cases manifest as a more subtle bronchopneumonia. Pneumonia resulting from the spread of infection along the intralobular airway results in fluffy or patchy infiltrates in the involved areas of the lung. A wide variety of bacteria and agents such as \textit{Chlamydophila}, \textit{Mycoplasma}, and \textit{Legionella} spp., viruses, and fungi may cause this pattern.

An interstitial pattern on a chest radiograph (Fig. 66.2) typically is caused by \textit{Mycoplasma} spp., viruses, or \textit{P. jiroveci}. The classic radiographic findings in PCP are bilateral interstitial infiltrates that begin in the perihilar region (Fig. 66.3). Radiographic manifestations of PCP can vary considerably, including normal appearance and lobar infiltrates, pleural effusions, hilar adenopathy, parenchymal nodules, and cavitary disease. Tiny nodules disseminated throughout both lungs represent a miliary pattern typical of granulomatous pneumonias, such as TB or fungal disease. The location of infiltrates may also suggest the cause. Aspiration pneumonia occurs in dependent areas of the lung, usually the superior segments of the lower lobes or posterior segments of the upper lobes. Infiltrates from pneumonias produced by hematogenous spread (eg, \textit{S. aureus}) tend to be multiple and peripheral. Apical infiltrates suggest TB.

The presence of additional radiographic features in association with infiltrates may suggest a specific cause. An infiltrate associated with hilar or mediastinal adenopathy suggests the presence of TB or fungal disease or may indicate pneumonia associated with a neoplasm. Bacteria most likely associated with cavitation (Fig. 66.4) are anaerobes, aerobic gram-negative bacilli, and \textit{S. aureus}. Cavitation also may be present in fungal disease or TB and with noninfectious processes (eg, malignancy and pulmonary vascular disease). Pneumatoceles or spontaneous pneumothorax may be seen in AIDS patients with FCP. Pleural effusions occur

\begin{figure}
\centering
\includegraphics[width=\textwidth]{image}
\caption{Posteroanterior chest radiograph reveals patchy interstitial infiltrates. Viruses and \textit{Mycoplasma} are the most likely causes in an otherwise healthy patient, but many bacterial organisms may also produce this pattern.}
\end{figure}
PART III  Medicine and Surgery  |  SECTION TWO  Pulmonary System

with a wide variety of organisms, including many types of pyogenic bacterial pneumonias, Chlamydophila and Legionella spp., and TB. Anaerobic infections associated with an effusion are especially prone to the development of empyema. The diagnosis and aspiration of pleural effusions can be aided by the use of bedside ultrasonography in the ED.

Radiographic findings are nonspecific for predicting a particular infective cause. Mycoplasma pneumonia may manifest as a dense infiltrate, or pneumococcal pneumonia may manifest as a diffuse interstitial infiltrate. Immunocompromised patients are particularly prone to having atypical radiographic appearances. Rarely, patients with a clinical picture strongly suggestive of pneumonia have a normal chest radiograph, and some are found to have an infiltrate within the next 24 to 48 hours. The absence of findings on a chest radiograph should not preclude the use of antimicrobial therapy in appropriate patients with a clinical diagnosis of pneumonia. Immunocompromised patients, older adults, and patients with significant comorbidities may be treated with empirical antibiotics in the setting of signs and symptoms indicating pneumonia, even with a negative chest radiograph.

Laboratory studies also are nonspecific for identifying the cause of pneumonia. Although the finding of a white blood cell (WBC) count greater than 15,000/mm³ increases the probability of the patient having a pyogenic bacterial cause rather than a viral or atypical cause, the predictive value of this finding depends on the stage of the illness and likely prevalences of various causes. This is neither sensitive nor specific enough to aid decisions regarding therapy in an individual patient. A WBC count may be helpful if it yields evidence of immunosuppression, such as neutropenia, or if it reveals lymphopenia that may indicate immunosuppression from AIDS. Basic metabolic panels may help identify patients with renal or hepatic dysfunction or metabolic acidosis associated with sepsis. These findings predict a complicated course and influence decisions regarding disposition, choice of antimicrobial agents, and dosages. The serum lactate dehydrogenase level is significantly elevated in AIDS patients with PCP compared with patients with non-PCP pneumonia. Inflammatory markers such as the erythrocyte sedimentation rate, and procalcitonin and C-reactive protein levels are not helpful in clinical decision making regarding pneumonia. The procalcitonin level has been suggested as a means to assess the likelihood of a bacterial cause, response to antimicrobial therapy, and prognosis. A procalcitonin strategy can slightly reduce antibiotic use without increased morbidity, but is only moderately sensitive for identifying bacterial pneumonia and has not been shown to add prognostic information beyond other risk stratification systems. Assessment of respiratory function with pulse oximetry is important in the evaluation of patients with pneumonia because the clinical assessment of oxygenation can be inaccurate. Pulse oximetry should be performed in any patient suspected to have pneumonia, and pneumonia should be considered in patients with low oxygen saturation.

Sputum Gram staining rarely results in a change in therapy or outcome. Correlation between the identification of pneumococcus on Gram staining and sputum culture results is poor, even when commonly used criteria for an adequate sputum specimen are applied (<five squamous epithelial cells and >25 WBCs/high-power field). Gram staining is even less likely to show gram-negative pathogens, such as H. influenzae, and should not be relied on to rule out a gram-negative cause. Empirical antimicrobial agents are usually highly clinically effective if chosen based on clinical information without sputum analysis. ATS/IDSA guidelines for the management of CAP support limiting sputum Gram staining and culture to patients with more severe disease or risk factors for unusual pathogens.

Confirmation of the diagnosis of PCP requires sputum induction and staining and, in some cases, further invasive procedures, such as bronchoscopy with bronchoalveolar lavage or biopsy.

Routine blood cultures are of essentially no value in immunocompromised adults with pneumonia, in whom there is a very low prevalence of bacteremia, and management is rarely changed based on the results. Follow-up of false-positive blood cultures is costly and labor-intensive and may lead to the unnecessary use of antibiotics, such as vancomycin or linezolid, when contaminant growth is initially reported as gram-positive cocci. Blood samples for culturing should be obtained from immunocompromised patients, those with severe sepsis or shock, or those with risk factors for endovascular infection (eg, prosthetic valves, IV drug use, cavitary infiltrates). When culture specimens are drawn, they should be obtained before the initiation of antibiotics, although antibiotics should not be delayed for this reason.
Patients with a pleural effusion larger than 5 cm on an lateral, upright, posterior-anterior chest radiograph should undergo diagnostic thoracentesis, with fluid sent for cell count, differential, pH (pH < 7.2 predicts the need for a thoracostomy tube), Gram staining, and culture. For most patients, thoracentesis can be safely deferred until after hospital admission. Patients in significant respiratory distress, however, or with evidence of tension and mediastinal shift, require emergent diagnostic and therapeutic thoracentesis.

Serologic tests are available for the diagnosis of many organisms, including C. pneumoniae, Legionella spp., and fungi. The use of serologic tests to determine the cause of pneumonia may be helpful retrospectively, but these usually require acute and convalescent serum titers and are of little use in the ED. Urine antigen tests for S. pneumoniae and Legionella are available and, in some facilities, results can be obtained within the time frame of an ED evaluation. It is not clear, however, that a positive result should prompt a change in empirical treatment. Rapid diagnostic tests for viral antigens are available for several viruses, including respiratory syncytial virus (RSV) and influenza. The test results may be useful for infection control decisions in hospitalized patients and may provide an indication for influenza therapy and family prophylaxis. Some commercially available rapid influenza tests are insensitive for certain strains. Rapid testing for respiratory viruses (ie, RSV, influenza, metapneumovirus, adenovirus, enterovirus) with a polymerase chain reaction assay is increasingly available to emergency clinicians to determine the specific cause of pneumonia and is more accurate than antigen tests.

**MANAGEMENT**

The possibility of communicable disease should prompt consideration for early isolation. Patients with a history of TB exposure or suggestive symptoms (eg, persistent cough, weight loss, night sweats, hemoptysis) or who belong to a group at high risk for TB (eg, homeless, IV drug user, alcoholic, HIV risk, immigrant from high-risk area) should be given a mask and placed in respiratory isolation before evaluation, including chest radiography. Because AIDS patients with pulmonary TB cannot be distinguished reliably from AIDS patients with other pulmonary infections at presentation, TB should be considered in all HIV-infected patients with respiratory complaints, and respiratory isolation should be initiated. EDs that frequently care for patients at risk for TB should consider triage protocols to identify these individuals rapidly before patients, visitors, or staff are unnecessarily exposed. Suspected infection with organisms transmitted by respiratory droplet (eg, influenza) should prompt infection control precautions, such as a mask being placed on the patient.

Antimicrobials should be administered in the ED for patients who are being admitted to the hospital. The timely administration of antimicrobials is associated with improved outcomes for hospitalized pneumonia patients, although confounding factors limit a full understanding of this relationship. Any presumed benefit of early antibiotic administration should be weighed against the risk of inappropriate use for patients in which the diagnosis is unclear. The antibiotics selected should cover the likely causes based on clinical, laboratory, radiologic, and epidemiologic information. The regimen should also be as selective as possible to avoid drug toxicity, emergence of resistance to broad-spectrum agents, and excessive cost.

The prevalence of drug-resistant S. pneumoniae (DRSP) has been increasing. In most areas of the United States, high-level penicillin resistance occurs in approximately 15% to 20% of outpatient pneumococcal sputum isolates. DRSP that is resistant to penicillin is usually resistant to other β-lactams, macrolides, tetracyclines, and trimethoprim-sulfamethoxazole (TMP-SMX). Extended-spectrum (or respiratory) fluoroquinolones, such as levofloxacin, are active against DRSP and other typical and atypical bacterial pathogens. Because the oral bioavailability of fluoroquinolones is high, oral therapy provides serum and tissue levels essentially equivalent to parenteral therapy. It is not clear, however, the extent to which in vitro resistance is related to adverse clinical outcome. Most cephalosporins and macrolides achieve adequate levels in serum and tissues to treat S. pneumoniae respiratory tract infections successfully, even if the laboratory reports that the organism is resistant.

CA-MRSA is the most common pathogen isolated in community-acquired skin and soft tissue infections. It causes severe, rapidly progressing pneumonia with sepsis, often in children or healthy young adults with influenza. CA-MRSA remains an uncommon cause of CAP but empirical coverage of MRSA should be strongly considered for patients with severe pneumonia associated with sepsis, especially those with likely influenza, contact with someone infected with MRSA, or radiographic evidence of necrotizing pneumonia. Antimicrobials with consistent in vitro activity against CA-MRSA isolates include vancomycin, TMP-SMX, tigecycline, linezolid, and ceftaroline. Although vancomycin is used most often for documented MRSA infections, vancomycin may be losing efficacy in light of increasing minimum inhibitory concentrations.

Appropriate agents for the outpatient treatment of adults with CAP include macrolides, doxycycline, and fluoroquinolones with enhanced activity against S. pneumoniae (Table 66.1). In patients properly identified as being at low risk for complications with careful outpatient follow-up, use of a macrolide such as azithromycin, 500 mg orally (PO) once, followed by 250 mg PO daily for

*Doses are for 70-kg adult with normal renal and hepatic function. DRSP, Drug-resistant S. pneumoniae; PO, orally.*
4 days, is preferred. Doxycycline is an alternative choice that has activity against some uncommon causes of pneumonia such as MRSA, but it has more side effects. For patients at higher risk of DRSP because of recent antibiotic use or comorbidities such as chronic heart, lung, liver, or renal disease, a respiratory fluoroquinolone should be considered. For patients who have received a fluoroquinolone within the previous few months, a combination of a macrolide plus a β-lactam agent (eg, high-dose amoxicillin [1 g tid], amoxicillin-clavulanate [2 g PO bid], or cefpodoxime) is appropriate. Levofloxacin, 750 mg daily for 5 days, doxycycline, 100 mg bid for 7 days, or a 5-day course of azithromycin is indicated for CAP. Admitted patients for the ICU for respiratory failure or pneumonia should be treated with oseltamivir during influenza season.

For patients whose illness is severe enough to necessitate hospital admission and parenteral antibiotics, a combination of a β-lactam agent, such as ceftriaxone, 1 g (IV) q24h (or cefotaroline, cefotaxime, ampicillin-sulbactam, or ertapenem), plus a macrolide (eg, azithromycin, 500 mg IV or PO daily) is the regimen recommended in ATS/IDSA guidelines.12 Alternatively, an extended-spectrum fluoroquinolone (eg, levofloxacin, moxifloxacin) can be given as monotherapy, but this regimen may be more likely to promote antimicrobial resistance. These regimens treat the most common bacterial pathogens, such as S. pneumoniae, and H. influenzae, and atypical pathogens, such as Mycoplasma, Chlamydia phila, and Legionella spp. B-Lactam monotherapy has been found to be noninferior to β-lactam–macrolide combination therapy or fluoroquinolone monotherapy in nonsevere CAP; it is a reasonable choice for patients without a specific reason to suspect atypical organisms.

Fluoroquinolones have some activity against TB and should be avoided in patients for whom TB is a possible cause because of the risk of obscuring the correct diagnosis and selection of resistant TB. IV azithromycin alone may be an option for patients with milder illness who are unlikely to be bacteremic; it does not achieve significant serum levels and lacks significant activity against many aerobic gram-negative bacilli and DRSP. If anaerobic organisms are suspected (eg, aspiration), clindamycin or metronidazole could be added to the regimen, or the regimen could include an antibiotic with anaerobic activity, such as ertapenem, ampicillin-sulbactam, piperacillin-tazobactam, tigecycline, or moxifloxacin (Table 66.2).

Seriously ill patients with severe sepsis or septic shock require aggressive fluid resuscitation and may benefit from more intensive management with vasopressors, transfusion, and inotropics. For severely ill and compromised patients are at relatively greater risk of infection with S. pneumoniae, aerobic gram-negative bacilli, S. aureus (including MRSA) and, in some areas, Legionella spp. For pneumonia patients admitted to an ICU, adequate activity against DRSP may be more important. Outcomes with severe pneumonia may be better with combination therapy.22 A third-generation cephalosporin or β-lactam or β-lactamase inhibitor can be combined with a macrolide or fluoroquinolone, and addition of vancomycin or linezolid should be considered for MRSA activity.

Patients with recent hospitalization, neutropenia, or underlying bronchiectasis are at increased risk of infection with P. aeruginosa. Empirical therapy should include two agents with extended gram-negative activity, including P. aeruginosa. Empirical regimens include cefepime, imipenem, meropenem, doripenem, or piperacillin-tazobactam, plus ciprofloxacin (high dose) or an aminoglycoside and macrolide. For life-threatening pneumonia in populations at risk for MRSA, the addition of vancomycin or linezolid may be considered.

Because HCAP is associated with higher mortality and a greater likelihood of unusual pathogens, the use of broader spectrum empirical therapy is often appropriate, usually with a combination of antimicrobials to increase the chance that at least one antibiotic will be active against the causative pathogen. The reflex broadening of empirical therapy for patients with risk factors for HCAP (see Box 66.1) has been called into question. Automatic application of the criteria for HCAP may result in the unnecessary overuse of antibiotics. It is recommended that the emergency clinician individualize the decision to initiate multidrug resistant empirical coverage in patients who are sufficiently ill or with multiple risk factors for HCAP. Such appropriate combinations include an antipseudomonal β-lactam agent (eg, piperacillin-tazobactam, cefepime, imipenem, meropenem) with an aminoglycoside or fluoroquinolone and vancomycin or linezolid for MRSA.22

For patients with AIDS, it is important to treat P. jiroveci and bacterial pathogens such as S. pneumoniae. TMP-SMX is the treatment of choice; the usual regimen is 15 mg/kg of TMP and 75 mg/kg of SMX daily qid, to be continued for 21 days, in addition to a regimen to cover CAP organisms.22 For most adult patients a

regimen of three ampules (80 mg of TMP–400 mg of SMX/ampule) qid is appropriate. For patients allergic to sulfa, options include clindamycin, 600 mg IV tid, plus primaquine, 30 mg PO daily. The addition of corticosteroids (prednisone, 40 mg PO bid) reduces mortality and clinical deterioration in patients with hypoxemia. Traditionally, this has been defined as a Pao2 less than 70 mm Hg or alveolar–arterial gradient greater than 35 mm Hg. In practice, pulse oximetry with an SaO2 ≤ 92% on room air or desaturation with exercise should warrant the initiation of corticosteroids. *Mycoplasma, Legionella,* and *Chlamydia spp.* are uncommon causes of severe pneumonia in AIDS patients, so empirical therapy with erythromycin or doxycycline is not routinely recommended.

**DISPOSITION**

There is tremendous variability among emergency clinicians in deciding whom to admit for pneumonia. The more common tendency is the overestimation of disease severity, leading to hospitalization of patients at low risk for death or serious complications. The decision to hospitalize a patient with pneumonia does not necessarily mean that a prolonged inpatient stay is required. Observation for 12 to 24 hours in the ED observation unit or hospital may allow the early discharge of certain moderate-risk patients. Inpatient treatment of pneumonia is 15 to 20 times more expensive per patient than outpatient treatment, and most patients are more comfortable in a home environment.

Although no firm guidelines exist regarding hospital admission, scoring systems may assist with hospitalization decisions. One commonly used system is based on the Pneumonia Patient Outcomes Research Team study, a prospectively validated predictive rule for mortality among immunocompetent adults with CAP. This model (also known as the pneumonia severity index [PSI]) suggests a two-step approach to assess risk. Patients in the lowest risk class appropriate for outpatient management are those younger than 50 years, without significant comorbid conditions (eg, neoplasm, congestive heart failure, cerebrovascular disease, renal disease, liver disease, HIV), and without findings that include altered mental status, pulse rate 125 beats/min or greater, respiratory rate 30 breaths/min or greater, systolic blood pressure less than 90 mm Hg, or temperature less than 35°C (95°F) or 40°C (104°F) or higher. Patients who do not fit the lowest risk category are classified into categories based on a scoring system that accounts for age, comorbid illness, physical examination findings, and laboratory abnormalities (Table 66.3). Hospitalization is recommended for patients with a score greater than 91, and brief admission or observation may be considered for patients with a score of 71 to 90. Although this method of assessing the likelihood of successful outpatient management is helpful, it can be cumbersome, is not modeled to predict acute life-threatening events, does not take into account dynamic evaluation over time, and has many important exceptions (eg, an otherwise low-risk patient with severe hypoxia who would be discharged by strict interpretation of this rule). Clinical judgment should supersede a strict interpretation of this scoring system. When emergency clinicians are educated, and provided with the patient’s risk score, use of the decision rule results in a significantly lower overall admission rate, cost savings, and similar quality of life scores compared with those for patients conventionally managed by their physicians. Additional discharge criteria include improving and stable vital signs over a several-hour observation period, ability to take oral medications, ambulatory pulse oximetry greater than 90%, home support, and access to follow-up.

A simpler tool is the CURB-65 rule. This mnemonic uses five simple criteria to determine patients at lower risk for adverse events—confusion, *uremia* (blood urea nitrogen > 20 mg/dL), *respiratory rate* greater than 30 breaths/min, *blood pressure* less than 90 systolic or less than 60 mm Hg diastolic, and *age* 65 years or older. The risk of 30-day mortality increases with more of these factors present: 0.7% with zero factors, 9.2% with two factors, and 57% with five factors. Patients with zero or one feature can receive outpatient care, those with two should be admitted, and ICU care should be considered for those with three or more factors. No randomized trials of hospital admission strategies have directly compared the PSI with the CURB-65 score. In a comparison of scores in the same population of CAP patients, the PSI yields a slightly higher percentage of patients in the low-risk category, with a similar low mortality rate.

The decision to admit a patient to the ICU is straightforward when patients are intubated or require vasopressors. It is more difficult to identify patients who do not require these interventions initially but may be at greater risk for deterioration and require a level of monitoring that may be beyond that available on the typical hospital ward. Objective criteria using the PSI (class V) and CURB-65 have been proposed but have not been prospectively validated for the ICU admission decision. When similar criteria were retrospectively studied in a cohort of CAP patients, they did not perform better than actual emergency clinician decisions. ATS/IDSA guidelines include criteria for defining severe CAP (Box 66.2), but these have not been validated. An ICU risk stratification score is abbreviated as SMART COP; intensive

Criteria for Severe Community-Acquired Pneumonia

**MINOR CRITERIA**
- Respiratory rate > 30 breaths/min
- PaO$_2$/FiO$_2$ ratio < 250
- Multilobar infiltrates
- Confusion, disorientation
- Uremia (BUN level > 20 mg/dL)
- Leukopenia (WBC count < 4000 cells/mm$^3$)
- Thrombocytopenia (platelet count < 100,000 cells/mm$^3$)
- Hypothermia (core temperature < 36°C [96.8°F])
- Hypotension requiring aggressive fluid resuscitation

**MAJOR CRITERIA**
- Invasive mechanical ventilation
- Septic shock with the need for vasopressors

**BOX 66.2**

Criteria for Severe Community-Acquired Pneumonia

**MINOR CRITERIA**
- Respiratory rate > 30 breaths/min
- PaO$_2$/FiO$_2$ ratio < 250
- Multilobar infiltrates
- Confusion, disorientation
- Uremia (BUN level > 20 mg/dL)
- Leukopenia (WBC count < 4000 cells/mm$^3$)
- Thrombocytopenia (platelet count < 100,000 cells/mm$^3$)
- Hypothermia (core temperature < 36°C [96.8°F])
- Hypotension requiring aggressive fluid resuscitation

**MAJOR CRITERIA**
- Invasive mechanical ventilation
- Septic shock with the need for vasopressors

BUN, Blood urea nitrogen; PaO$_2$/FiO$_2$, arterial oxygen pressure/fraction of inspired oxygen; WBC, white blood cell.

*Other criteria to consider include hypoglycemia (in patients who do not have diabetes), acute alcoholism or alcoholic withdrawal, hyponatremia, unexplained metabolic acidosis or elevated lactate level, cirrhosis, and asplenia.

*As a result of infection alone.

Empirical antimicrobial therapy should be started in the ED for patients admitted with pneumonia.

Empirical therapy should treat the most likely pathogens for the clinical situation, such as *S. pneumoniae*, *H. influenzae*, *M. pneumoniae*, and *C. pneumoniae*, and should be consistent with current national treatment guidelines, such as those from the ATS/IDSA.

HIV or other immunosuppressive conditions should be considered for all patients in whom pneumonia is suspected.

Disposition is dictated by the patient’s underlying medical conditions, severity of illness, likelihood of clinical deterioration, and feasibility of home care and outpatient follow-up.

No characteristic radiographic pattern is pathognomonic for a specific pneumonia pathogen.

*Legionella* should be suspected in patients with gastrointestinal or neurologic symptoms presenting with pneumonia.

CHAPTER 66: QUESTIONS & ANSWERS

66.1. Which of the following statements regarding community-acquired pneumonia (CAP) is true?  
A. Among hospitalized adults with CAP, Streptococcus pneumoniae and Haemophilus influenzae account for most cases.  
B. Chlamydia pneumonia is the most common atypical agent causing severe pneumonia.  
C. Clinical history and prodrome often lead to organism identification.  
D. S. pneumoniae is the most common pathogen among those requiring intensive care unit (ICU) admission.  
E. Viral causes are seen in approximately 40% of cases.  

Answer: D. Pneumococcus and H. influenzae account for 25% of cases of hospitalized CAP. Viral causes are seen in approximately 18% of cases, although there is uncertainty about this figure because most patients are not tested for specific viruses. Legionella, rather than Chlamydia, causes the most severe pneumonia among the atypicals. There is no clinical history or symptom complex that reliably allows organism identification.

66.2. Which of the following associations is correct?  
A. Cytomegalovirus (CMV) pneumonia—immunosuppression, adults  
B. Influenza pneumonia—summer, adults  
C. Mycoplasma pneumonia—winter, infants  
D. Parainfluenza pneumonia—spring, infants  
E. Varicella zoster pneumonia—winter, military recruits  

Answer: A. CMV pneumonia rarely occurs in healthy people and is typically seen in the immunosuppressed patient, such as a transplant patient. Varicella pneumonia is associated with smoking and pregnancy in adults. Influenza and parainfluenza typically occur in winter months. Mycoplasma pneumonia is typically a disease of adolescents and adults.

66.3. A 26-year-old landscaper presents with chronic cough with intermittent fevers. He has no other past medical history. The symptoms began 2 months ago after a 7- to 10-day prodrome of cough with productive sputum, for which he received a macrolide without improvement. Physical examination and vital signs are normal. The chest radiograph is shown here. What is the most likely cause for this process?
A. *Histoplasma capsulatum*
B. *Klebsiella pneumonia*
C. *Pneumocystis jiroveci*
D. Sarcoidosis
E. *Streptococcus pneumoniae*

**Answer:** C. *Histoplasma capsulatum, Blastomyces dermatitidis*, and *Coccidioides immitis* are fungi present in the soil in various geographic areas. They are most common in people engaged in soil-disturbing activities, such as construction or dirt bike racing trials, and should be considered when patients fail to respond to antibacterial treatment. The chest radiograph shows asymmetric hilar adenopathy and left-sided cavitation with fibrotic changes. Sarcoidosis would clinically show symmetrical adenopathy. *Klebsiella* is rarely seen in healthy adults. *Pneumocystis jiroveci* would be a possibility if the patient were known or suspected to be infected with human immunodeficiency virus (HIV), but a 2-month history would be uncommon.

**66.4.** The potential for opportunistic pulmonary infection can be predicted by an absolute CD4 lymphocyte count less than which of the following?
A. 50/mm³
B. 100/mm³
C. 150/mm³
D. 200/mm³
E. 250/mm³

**Answer:** D. This count is often found in patients with HIV infection or may be estimated by a peripheral total lymphocyte count less than 1000/mm³.

**66.5.** A 60-year-old man with a past medical history of adult-onset diabetes controlled with glyburide presents with cough, weakness, and purulent sputum production. Vital signs are temperature 38.3°C (101°F) oral, heart rate, 130 beats/min, blood pressure, 85/50 mm Hg, respiratory rate, 30 breaths/min, and oxygen saturation, 91%. The chest radiograph reveals a consolidated left lower lung (LLL) pneumonia. What is the most appropriate antibiotic therapy?
A. Ceftriaxone plus levofloxacin plus vancomycin
B. Ceftriaxone with a macrolide
C. Fluoroquinolone only
D. Trimethoprim-sulfamethoxazole (TMP-SMX)
E. Vancomycin only

**Answer:** A. In patients requiring hospitalization for CAP, coverage for CAP would typically be with a fluoroquinolone or combination of a macrolide with a β-lactam. Because this patient has signs of severe sepsis, consideration should be given to the addition of an agent for methicillin-resistant *Staphylococcus aureus* (MRSA; vancomycin) in addition to CAP coverage.

**66.6.** Which of the following causative agents of pneumonia would be an indication for respiratory isolation when suspected?
A. *Histoplasma capsulatum*
B. *Mycobacterium tuberculosis*
C. *Pneumocystis jiroveci*
D. *Staphylococcus aureus*
E. *Streptococcus pneumoniae*

**Answer:** B. Any patient for whom tuberculosis is a suspected possibility should be placed in respiratory isolation in a negative-pressure room until it can be ruled out by acid-fast bacilli (AFB) smears. The other listed organisms do not require respiratory isolation.
Pleural disease emergency presentations range in severity from asymptomatic pleural effusion to tension pneumothorax. This chapter reviews the two most common nontraumatic pleural problems, spontaneous pneumothorax and pleural inflammation with effusion.

SPONTANEOUS PNEUMOTHORAX

Principles

Background and Importance

Pneumothorax is defined as the presence of air in the intrapleural space and can range from a benign to a life-threatening process. A spontaneous pneumothorax occurs in the absence of any external precipitating factor, traumatic or iatrogenic. Primary spontaneous pneumothorax occurs in individuals without clinically apparent lung disease. Secondary spontaneous pneumothorax arises in the context of an underlying pulmonary disease process. Tension pneumothorax is a life-threatening complication resulting from pressure in the pleural cavity causing hemodynamic compromise.

Primary spontaneous pneumothorax typically occurs in healthy young men of taller than average height and is approximately three times more common in men than women. Factors associated with primary spontaneous pneumothorax include smoking cigarettes and cannabis, as well as changes in ambient atmospheric pressure. Familial patterns suggest an inherited propensity in some cases of primary spontaneous pneumothorax. Mitral valve prolapse and Marfan syndrome are also associated with spontaneous pneumothorax.

Secondary spontaneous pneumothorax can occur in the context of many underlying pulmonary diseases (Box 67.1). The incidence of secondary spontaneous pneumothorax is three times higher in men. The most common condition associated with secondary spontaneous pneumothorax is chronic obstructive pulmonary disease (COPD), and patients with severe COPD are at highest risk. Spontaneous pneumothorax is relatively common in patients with cystic fibrosis and is also a known complication of Pneumocystis jiroveci pneumonia in patients with acquired immunodeficiency syndrome. Malignancy, especially in patients with lung metastases, is a condition associated with secondary spontaneous pneumothorax.

In developing countries, tuberculosis and lung abscess remain leading causes of secondary spontaneous pneumothorax. Catamenial pneumothorax is a rare condition in which recurrent spontaneous pneumothorax occurs in association with menses, typically within 72 hours of onset. Although it is termed thoracic endometriosis syndrome and often responds to ovulation-suppressing medications, the exact cause of catamenial pneumothorax is uncertain.

Spontaneous pneumothorax is rare in children. There is a male predominance in the pediatric population. Common causes of secondary spontaneous pneumothorax in children include asthma, cystic fibrosis, foreign body aspiration, and connective tissue disease, such as that seen with juvenile idiopathic arthritis. The principles of diagnosis, imaging, treatment, and surgical management for pediatric primary spontaneous pneumothorax are similar to those for adult pneumothorax.

Anatomy and Physiology

Under normal conditions, the visceral and parietal pleurae lie in close apposition, with only a potential space between them. Normally, intrapleural pressure is negative (less than atmospheric) during expiration. Intrabronchial and intraalveolar pressures are negative during inspiration and positive during expiration. The alveolar walls and visceral pleura form a barrier that separates the intrapleural and intraalveolar spaces and maintains the pressure gradient. If a defect occurs in this barrier, air enters the pleural space until the pressures equalize or the communication seals. In spontaneous pneumothorax, disruption of the alveolar-pleural barrier can occur when a subpleural bulla (or bleb) ruptures into the pleural space. Underlying lung disease and chronic inflammation also weaken the alveolar-pleural barrier. Other factors, including increased intrabronchial and intraalveolar pressures generated by bronchospasm and coughing, also play a role.

With the loss of negative intrapleural pressure in the unilateral hemithorax, the ipsilateral lung collapses. A large pneumothorax results in restrictive ventilation impairment, with reduced vital capacity, functional residual capacity, and total lung capacity. Shunting of blood through nonventilated lung tissue may result in acute hypoxemia although, over time, this effect is mitigated by compensatory vasoconstriction in the collapsed lung.

In tension pneumothorax, the alveolar-pleural defect acts as a one-way valve, allowing air to pass into the pleural space during inspiration and trapping it there during expiration (Fig. 67.1). This trapping leads to progressive accumulation of intrapleural air and increasingly positive intrapleural pressure, causing compression of the contralateral lung, with asphyxia and worsening hypoxia. Increasing intrapleural pressure impairs venous return to the heart and, if allowed to progress, cardiovascular collapse and death ensue.

Clinical Features

Symptoms of primary spontaneous pneumothorax typically begin suddenly while the individual is at rest. Ipsilateral chest pain and dyspnea are the most common symptoms. At the outset, the pain is typically pleuritic in nature (ie, often described as sharp and made worse with deep inspiration), but it often evolves over time into a dull steady ache. Although patients frequently describe shortness of breath, extreme dyspnea is uncommon in the absence of underlying lung disease or tension pneumothorax. Symptoms are often mild and patients may wait several days before they seek medical attention. Without treatment, symptoms often resolve spontaneously within 24 to 72 hours, although the pneumothorax is still present.

Physical findings tend to correlate with the degree of symptoms. Sinus tachycardia is the most common early physical
finding. With a large pneumothorax, hypoxia and decreased or absent breath sounds with hyperresonance to percussion may be present. In children, breath sounds are distributed throughout the thorax, which makes hearing a decrease in breath sounds on the affected side more challenging. Other classic signs of a large pneumothorax include unilateral enlargement of the hemithorax, decreased excursion with respirations, absent tactile fremitus, and inferior displacement of the liver or spleen. Absence of any or all of these findings does not exclude pneumothorax, however, and a chest radiograph should be obtained when pneumothorax is suspected.

With tension pneumothorax, signs of asphyxia and decreased cardiac output develop. Tachycardia and hypoxia are common. Hypotension is a late and ominous finding. Distention of the jugular veins is common but may be difficult to detect. Displacement of the trachea to the contralateral side is classically described but is an uncommon finding, usually occurring only in the immediately preterminal phase of the pneumothorax, if at all. Its absence should not be considered evidence that a tension phenomenon is not present.

In patients with significant underlying lung disease, pneumothorax manifests differently. Because of poor pulmonary reserve, dyspnea is nearly universal, even when the pneumothorax is small, and symptoms tend not to resolve on their own. Physical findings, such as hyperexpansion and distant breath sounds, often overlap considerably with the underlying lung disease, making the clinical diagnosis difficult. The diagnosis of pneumothorax should be considered whenever a patient with COPD or significant underlying lung pathology experiences an exacerbation of dyspnea, and we recommend obtaining a chest radiograph in most cases of COPD exacerbations. In children, because spontaneous pneumothorax is relatively rare, routine chest radiography is not recommended but should be performed if signs and symptoms warrant further investigation.

### Differential Diagnoses

The differential diagnosis of pneumothorax includes numerous conditions associated with chest pain and dyspnea. Among the most important is pulmonary embolism (PE), which may manifest in a similar fashion, with unilateral pleuritic chest pain. Most pleural-based processes (eg, pneumonia, embolism, tumor) have characteristic radiographic findings. Rarely, pneumothorax may mimic an acute myocardial infarction with electrocardiographic changes simulating an acute injury pattern or pericarditis. Pericardial effusion with or without tamponade can present with dyspnea, chest pain, and tachycardia but can be readily distinguished from pneumothorax with bedside cardiac ultrasound.

Spontaneous pneumomediastinum is a closely related clinical entity, diagnosed by the presence of subcutaneous emphysema and the finding of mediastinal air on the chest x-ray. In contrast to spontaneous pneumothorax, spontaneous pneumomediastinum typically occurs during exertion, particularly after a strenuous Valsalva maneuver. Most cases of spontaneous pneumomediastinum occur in the absence of known underlying disease and have a benign course. Secondary causes of pneumomediastinum (eg, Boerhaave’s syndrome) are more serious, and treatment is aimed at the underlying disorder.

Spontaneous hemothorax is a rare but potentially serious condition that occurs when collapse of the lung is associated with the rupture of a vessel in a parietopleural adhesion. The clinical presentation is similar to that of spontaneous pneumothorax but may be accompanied by symptoms and signs of hemorrhagic shock. Treatment entails large-caliber tube thoracostomy to evacuate the pleural space, reexpand the lung, and tamponade of bleeding.

### Diagnostic Testing

Although suggested by the patient’s history and physical examination, the diagnosis of pneumothorax is generally made with imaging, including chest radiography, ultrasound, and chest computed tomography (CT). The classic radiographic appearance is that of a thin, visceral pleural line lying parallel to the chest wall, separated by a radiolucent band devoid of lung markings. The average width of this band can be used to estimate the size of the pneumothorax, such as with the Rhea method (Fig. 67.2). However, precise quantification is often inaccurate and, in general, it is more reasonable simply to characterize the pneumothorax as small, moderate, large, or total. British Thoracic Society guidelines define size based on measurement of the interpleural distance at the level of the hilum: small, less than 1 cm; moderate, 1 to 2 cm; and large, more than 2 cm. The American College of Chest Physicians measures from the apex to the cupula—small is less than 3 cm, and large is more than 3 cm. The estimated size of the
pneumothorax and the patient’s clinical status can be useful in guiding management decisions.

Tension pneumothorax is a clinical diagnosis, and delay in treatment to obtain radiographic confirmation is inadvisable. When the diagnosis of tension pneumothorax is not apparent clinically and a chest radiograph is obtained, the classic appearance is one of complete lung collapse, with gross distention of the thoracic cavity on the affected side and shift of mediastinal structures across the midline (Fig. 67.3A). In patients with underlying pulmonary disease, however, pleural adhesions and lack of lung elasticity may mask the fact that a pneumothorax is under significant positive pressure. In critically ill patients for whom only a supine chest radiograph can be obtained, the finding of a deep sulcus (ie, a deep lateral costophrenic angle) can suggest the presence of pneumothorax on that side (see Fig. 67.3A).

Special care should be taken in viewing the chest radiographs of patients with underlying lung disease. In patients with COPD, the relative paucity of lung markings makes pneumothorax more difficult to detect. At the same time, giant bullae may simulate the radiographic appearance of pneumothorax. A clue to differentiating a pneumothorax from a giant bulla is that the former tends to run parallel to the chest wall, whereas the latter tends to have a more concave appearance. When the diagnosis is unclear, CT can differentiate between the two entities, as well as evaluate underlying pulmonary pathology. We recommend obtaining a chest CT in patients with significant underlying pulmonary disease who present with new dyspnea or hypoxia and nondiagnostic chest radiography. Chest CT with contrast is necessary to rule out PE but a noncontrast chest CT can identify occult pneumonia, pneumothorax, or progression of underlying disease. CT can also be used in primary spontaneous pneumothorax to detect emphysematous changes, predict the likelihood of recurrence, and guide intervention decisions. Occult pneumothorax, a pneumothorax identified only on a chest CT scan, is an increasingly common phenomenon, given the increase in the use of CT. Typically, small occult pneumothoraces can be managed expectantly in stable patients. Ventilated patients with an occult pneumothorax require close monitoring with serial radiographs.

Point of care thoracic ultrasound is increasingly used in the diagnosis of pneumothorax. Bedside thoracic ultrasound is more sensitive than chest radiography for the diagnosis of pneumothorax. In addition to routine use for the diagnosis of spontaneous pneumothorax, thoracic ultrasound can be used to evaluate for postprocedural pneumothorax and the diagnosis of occult pneumothorax in critically ill patients. In a normal lung, the closely opposed visceral and parietal pleura create the appearance of shimmering or sliding of the pleural interface during respiration. Visualization of lung sliding at the pleural line effectively rules out pneumothorax in the area being scanned. Absence of pleural sliding is suggestive of pneumothorax. Identification of the lung point, or the boundary between normal lung and pneumothorax, is highly specific for the detection of pneumothorax. See Video 67.1. Caution should be used in patients with underlying pleural disease because false-positive results can occur in patients with pleural pathology, including blebs, fibrosis, or history of pleurodesis or pneumonectomy. In addition, absence of lung sliding is seen over the nonaerated hemithorax after mainstem bronchus intubation. Assessment of lung sliding is optimally performed with a high-frequency linear transducer or curvilinear transducer set to a shallow depth (see Fig. 67.3B). Further information regarding performing and interpreting bedside thoracic ultrasound can be found in Chapter e5.

**Management**

If the clinical circumstances suggest tension pneumothorax, treatment should be initiated prior to definitive diagnosis by chest radiography. As soon as tension pneumothorax is suspected clinically or based on the absence of lung sliding on ultrasound, the pleural space should be decompressed. This decompression may be accomplished by insertion of an intravenous catheter followed by tube thoracostomy or immediate tube thoracostomy, depending on the availability of equipment and expertise of the provider. The diagnosis is confirmed by the hiss of air escaping under positive pressure as the needle or chest tube enters the pleural space. Needle decompression is only a temporizing procedure, and definitive management requires prompt tube thoracostomy. In these patients, the needle and catheter may be of insufficient length to reach the pleural space, and a longer needle may be required. If needed, measurement of the depth from the skin surface to the pleural line can be obtained via ultrasound.

The management of spontaneous pneumothorax has two goals: (1) to evacuate air from the pleural space; and (2) to prevent recurrence. Pursuit of the latter goal extends beyond the realm of the emergency department (ED) but may influence the initial approach to management. Therapeutic options for the treatment of pneumothorax range from simple observation or aspiration with a catheter to video-assisted thoracoscopic surgery or thoracotomy. Decisions should be individualized, with consideration of several factors, including size of the pneumothorax, severity of signs, presence of underlying pulmonary disease, other comorbidities, history of previous pneumothoraces, patient reliability, degree and persistence of the air leak, and available follow-up monitoring.
In patients with a first episode of spontaneous pneumothorax without underlying lung disease, we recommend initial needle aspiration with an intravenous catheter. Aspiration is typically performed with a 16- or 18-gauge needle and three-way stopcock; the catheter may be left in during a 4- to 6-hour period of observation or removed after aspiration. If 6 hours after aspiration the chest radiograph shows no reaccumulation of the pneumothorax, the patient can be discharged home, with the same caveats that apply to patients managed with observation alone.

Alternatively, patients with large, primary spontaneous pneumothoraces can be initially managed by placement of a small-bore chest tube or catheter. Limited data have suggested that pigtail chest catheters, which are placed using a Seldinger technique over a guidewire, have similar outcomes to the use of small-bore chest tubes. Traditionally, patients with indwelling chest tubes or

**Fig. 67.3.** A, Radiograph of tension pneumothorax, with mediastinal shift to the left. B, Ultrasound demonstrating location of pleural line. Lung sliding is dynamic and visualized in real time as shimmering or sliding of the pleural line.

For otherwise healthy young patients with a small primary spontaneous pneumothorax (ie, pleural line 1–2 cm from the chest wall as measured on chest x-ray) and minimal symptoms, supplemental oxygen and observation alone may be appropriate. The intrinsic reabsorption rate ranges from 1% to 2%/day, a rate that is accelerated significantly with the administration of 100% oxygen. Although there are no evidence-based guidelines, we recommend observing these patients in the ED for a 4- to 6-hour period. This observation period also can occur in an ED-based observation unit. A repeat chest radiograph obtained before discharge should confirm that there is no interval worsening in the size of the pneumothorax.

For primary spontaneous pneumothoraces that are larger in size (ie, >2–3 cm) therapeutic options include needle aspiration or placement of a small bore (8–14 Fr) chest tube or chest catheter (eg, pigtail).
Background and Importance

Pleural inflammation and effusion

Principles

Background and Importance

Pleural effusion implies the presence of an abnormal collection of fluid in the pleural space. The most common cause of pleural effusions in the West countries is congestive heart failure, followed by malignancy, bacterial pneumonia, and PE. Tuberculosis remains the leading cause of pleural effusions in most of the developing world. Other conditions commonly associated with pleural effusions include viral infections, cirrhosis, nephrotic syndrome, uremia, ovarian hyperstimulation syndrome, collagen vascular diseases, myxedema, and intra-abdominal processes. Esophageal perforation is a rare but uniquely morbid cause of a pleural effusion.
Pleuritis (also referred to as pleurisy) is a nonspecific term denoting inflammation of the pleurae. Pleuritis is a common presentation for a range of infectious and inflammatory disease processes, ranging from self-limited viral syndromes to chronic illnesses, such as systemic lupus erythematosus. Pleuritis can occur with or without significant accumulation of fluid in the pleural space.

A pleural effusion associated with bacterial pneumonia or lung abscess is termed a parapneumonic effusion. The term pleural empyema (or pyothorax) implies the presence of actual pus in the pleural space. Fluid that is anatomically confined and not freely flowing within the pleural space is termed a loculated effusion. Loculated effusions occur when there are adhesions between the visceral and parietal pleurae. Traumatic hemothorax as a distinct type of pleural effusion is approached separately.

Anatomy and Physiology

Under normal circumstances, a thin layer of fluid lies between the visceral and parietal pleurae. Pleural fluid is produced from systemic capillaries at the parietal pleural surface and absorbed into pulmonary capillaries at the visceral pleural surface. Although lymphatics also play an important role in removing pleural fluid, the direction of pleural fluid flow is normally governed by the difference in hydrostatic pressure between the systemic and pulmonary circulations (Fig. 67.4). Under normal circumstances, pleural fluid exists in a dynamic equilibrium, with approximately 1 L of fluid traversing the pleural space over 24 hours, but the net accumulation of fluid in the pleural space is small ($\approx 0.1–0.2$ mL/kg body weight) and clinically insignificant. Pleural effusion develops when the influx of fluid into the pleural space exceeds the efflux.

Pathophysiology

Pleural effusions classically are divided into two groups—transudates and exudates—according to the composition of the pleural fluid (Box 67.2). Transudates are essentially ultrafiltrates of plasma, containing very little protein. A transudative effusion develops due to an increase in hydrostatic pressure or decrease in oncotic pressure within the pleural microvessels. The most common cause of transudative effusion is congestive heart failure, with its associated increase in hydrostatic pressure. Patients with severe malnutrition develop transudative effusions because of...
profound hypoalbuminemia and loss of plasma oncotic pressure. Certain conditions, such as hepatic cirrhosis and nephrotic syndrome, may be associated with an increase in hydrostatic pressure and a loss of plasma oncotic pressure.

Exudates, in contrast, contain relatively high amounts of protein, reflecting an intrinsic abnormality of the pleurae. Any pulmonary or pleural process associated with inflammation can result in an exudative effusion. The most common exudative effusion is a parapneumonic effusion, in which infection of the adjacent lung elicits an intense pleural inflammatory response. Malignant effusions are the second most common form of exudative effusion and often reflect alterations in pleural permeability and problems with lymphatic drainage. Exudative effusions also may arise in response to inflammatory processes in the abdomen, such as pancreatitis or subphrenic abscess. As an exudative effusion is reabsorbed, the fibrinous tissue left behind gives rise to in pleural adhesions.

Some pleural effusions can have exudative and transudative characteristics. For example, in the case of PE, the pathogenesis of a pleural effusion may be multifactorial, reflecting increased pulmonary vascular pressure (a transudative process) and ischemia and inflammation of the pleural membrane (an exudative process).

Massive effusions (>1.5–2 L) are usually associated with malignancy but also can arise in the setting of heart failure and other conditions of volume overload. Massive effusions restrict respiratory movement, compress the lung parenchyma, and result in intrapulmonary shunting. In extremely rare cases, tension hydrothorax can develop, with a mediastinal shift and circulatory collapse.

Clinical Features

Small pleural effusions often are entirely asymptomatic. Pleural inflammation, with or without effusion, is heralded by typically pleuritic pain (ie, worse with deep breathing) or pain referred to the shoulder. It is generally not until the volume of pleural fluid in an adult reaches at least 500 mL that dyspnea becomes apparent.

Physical findings also depend on the size of the effusion. A pleural friction rub may be the only finding in a patient with isolated pleurisy, whereas with massive effusions, signs of cardiovascular pulmonary compromise may be present. Classic physical signs of pleural effusion include diminished breath sounds, dullness to percussion, and decreased tactile fremitus. The simple technique of auscultatory percussion (ie, percussing the chest while listening for dullness with the stethoscope) may be even more sensitive and specific for the physical diagnosis of pleural effusion. Egophony and enhanced breath sounds are often appreciated at the superior border of the effusion because of underlying atelectatic lung tissue.

Differential Diagnosis

The differential diagnosis of pleural effusion includes a wide variety disease processes characterized by dyspnea and/or chest pain, ranging from congestive heart failure and volume overload to pneumonia, PE, and pericardial effusion. Of note, many of these conditions are associated with and may coexist with pleural effusion. In any case, the presence of pleural effusion requires thoughtful consideration of the underlying disease process. Specifically, an unexplained pleural effusion should raise concern for malignancy and requires follow-up.

Diagnostic Testing

When clinically suspected, the diagnosis of pleural effusion should be confirmed by chest radiography. A volume of approximately 200 mL is required before pleural effusion can be reliably demonstrated on an upright, frontal chest radiograph; a lesser amount of fluid may be visible in the posterior costophrenic gutter on a lateral projection. The classic radiographic appearance of a pleural effusion is blunting of the costophrenic angle. With larger effusions, the hemidiaphragm may be completely obscured, typically with an upwardly concave pattern, because pleural fluid tends to layer higher laterally than centrally. Pleural fluid can also extend up a major fissure and appear as a homogeneous density in the lower portion of the lung field. Massive pleural effusions can completely opacify the hemithorax (so-called white-out).

In the recumbent patient, free pleural fluid gravitates superiority, laterally, and posteriorly and thus may not be clearly discernible on a supine radiograph. If the effusion is large enough, diffuse haziness or partial opacification of a hemithorax may be seen. Other findings on the supine radiograph may include apical capping, obscuring of the hemidiaphragm, and/or a widened minor fissure. Some pleural effusions can be challenging to diagnose on plain radiographs. Clues to the presence of a subpneumonic effusion include an apparent shift of diaphragmatic dome toward the lateral chest wall and, when located on the left side, a radiodense gap between the gastric bubble and aerated lung. Loculated fluid in a pleural fissure may assume a fusiform appearance and can simulate a mass (Fig. 67.5A and B). The lateral recumbent view, although historically useful for demonstrating small loculated effusions, has been largely replaced by ultrasound or CT.

Thoracic ultrasound is more sensitive than chest radiography in diagnosing and estimating the size of pleural effusions. Sonographically, pleural effusions typically appear as hypoechoic fluid above the diaphragm and are best visualized with a curvilinear probe in the midaxillary line (see Fig. 67.5C). Not all pleural fluid is hypoechoic; hemorhax or pyothorax may appear heterogeneous. Often, compressed lung or pleural adhesions can be visualized within the effusion, and careful observation of these findings, as well as the location of the diaphragm, liver, or spleen, can aid in the correct localization for thoracentesis or tube thoracostomy. If available in the ED, ultrasound-guided thoracentesis should be performed to decrease the risk of complications such as pneumothorax.

CT can detect as little as 3 to 5 mL of pleural fluid and is the gold standard for the diagnosis of small pleural effusions. CT is particularly useful in distinguishing between pleural and parenchymal disease to help identify an underlying cause (eg, PE, malignancy), quantify the volume of pleural effusion, and guide thoracocentesis. In the recumbent patient, free pleural fluid gravitates superiority, laterally, and posteriorly and thus may not be clearly discernible on a supine radiograph. If the effusion is large enough, diffuse haziness or partial opacification of a hemithorax may be seen. Other findings on the supine radiograph may include apical capping, obscuring of the hemidiaphragm, and/or a widened minor fissure. Some pleural effusions can be challenging to diagnose on plain radiographs. Clues to the presence of a subpneumonic effusion include an apparent shift of diaphragmatic dome toward the lateral chest wall and, when located on the left side, a radiodense gap between the gastric bubble and aerated lung. Loculated fluid in a pleural fissure may assume a fusiform appearance and can simulate a mass (Fig. 67.5A and B). The lateral recumbent view, although historically useful for demonstrating small loculated effusions, has been largely replaced by ultrasound or CT.

Thoracic ultrasound is more sensitive than chest radiography in diagnosing and estimating the size of pleural effusions. Sonographically, pleural effusions typically appear as hypoechoic fluid above the diaphragm and are best visualized with a curvilinear probe in the midaxillary line (see Fig. 67.5C). Not all pleural fluid is hypoechoic; hemorhax or pyothorax may appear heterogeneous. Often, compressed lung or pleural adhesions can be visualized within the effusion, and careful observation of these findings, as well as the location of the diaphragm, liver, or spleen, can aid in the correct localization for thoracentesis or tube thoracostomy. If available in the ED, ultrasound-guided thoracentesis should be performed to decrease the risk of complications such as pneumothorax.

CT can detect as little as 3 to 5 mL of pleural fluid and is the gold standard for the diagnosis of small pleural effusions. CT is particularly useful in distinguishing between pleural and parenchymal disease to help identify an underlying cause (eg, PE, malignancy), quantify the volume of pleural effusion, and guide thoracocentesis.
If the diagnosis of a malignant pleural effusion is being considered, pleural fluid should be submitted for cytologic examination. Contrary to popular belief, the sensitivity for diagnosis of pleural malignancy does not depend on the volume of pleural fluid extracted during thoracentesis.

**Management**

Most pleural effusions do not require emergent drainage, and there are few indications for therapeutic thoracentesis in the ED. For patients with massive effusions (ie, >1.5–2 L), urgent thoracentesis may stabilize respiratory or circulatory status. Patients with empyema require timely chest tube drainage in the ED or operating room to prevent complications. In most other cases, the timing of therapeutic thoracentesis can be individualized. For example, therapeutic thoracentesis would be reasonable to perform in the ED for an oncology patient with a recurrent effusion if symptomatic relief will allow the patient to be discharged.

Relative contraindications to thoracentesis include coagulopathy and other bleeding disorders. Consider the risks and benefits of a procedure prior to initiating in the ED. Pleural adhesions are also a relative contraindication to thoracentesis because of the
Following a diagnostic or therapeutic thoracentesis, a chest radiograph should be obtained to evaluate for iatrogenic pneumothorax. Other potential complications of thoracentesis include hemothorax, lung laceration, shearing of the catheter tip, infection, and transient hypoxia due to ventilation-perfusion mismatch. Postexpansion pulmonary edema is a rare occurrence, except when large volumes (>1500 mL) are drained in one session. Hypotension can occur after the removal of a large volume of fluid, particularly in patients who are already intravascularly volume-depleted.

Disposition

The natural history of pleural disease is determined largely by the underlying diagnosis, and the decision to admit a patient with pleural disease to the hospital must be individualized, taking into account the patient’s respiratory and hemodynamic status and predicted clinical course. For example, small pleural effusions are common after abdominal surgery and in the postpartum state, but they almost always resolve spontaneously within a few days. Viral pleuritis, with or without effusion, is generally self-limited and resolves without specific treatment. In patients with congestive heart failure, pleural effusions generally respond well to diuretic therapy, but may persist in patients with poorly compensated disease. In nearly 20% of pleural effusions, no definitive diagnosis can be established, even after extensive investigation. A sizable percentage of these effusions are probably caused by viral infections, and most of these resolve spontaneously without sequelae.

Parapneumonic effusions contribute significantly to morbidity and mortality. For this reason, the presence of a parapneumonic effusion is an indication to hospitalize a patient with community-acquired pneumonia.21 Empyema will develop in 5% to 10% of patients with a parapneumonic effusion, and early surgical drainage results in better outcomes than conservative management.22

Pleural effusions associated with malignancy are a marker of significant morbidity. The presence of a malignant effusion indicates disseminated disease, and most of the malignancies that cause pleural effusions—such as lymphoma and carcinoma of the lung, breast, or ovary—are not curable at this stage. Therapeutic thoracentesis can relieve dyspnea in the short term, but malignant effusions tend to be recurrent, often rapidly so. That said, control of pleural effusions can improve quality of life in these patients. Strategies for managing recurrence include chemical or mechanical pleurodesis to obliterate the pleural space and placement of a permanent catheter or pleuroperitoneal shunt to provide continual drainage.

CHAPTER 67: QUESTIONS & ANSWERS

67.1. What is the most common condition associated with secondary spontaneous pneumothorax in adults?
A. Chronic obstructive pulmonary disease
B. Collagen vascular disease
C. Pneumocystis pneumonia
D. Pulmonary malignancy
E. Severe asthma exacerbation

Answer: A. Chronic obstructive pulmonary disease is the most common condition associated with secondary spontaneous pneumothorax, although all the conditions listed may also be causes.

67.2. Which of the following describes intrapleural pressure in relation to atmospheric pressure during normal spontaneous ventilation?
A. Inspiration, positive; expiration, negative
B. Inspiration, positive; expiration, positive
C. Inspiration, negative; expiration, negative
D. Inspiration, negative; expiration, positive
E. The relationship is variable and altitude-dependent.

Answer: C. In relation to atmospheric pressure, normal intrapleural pressure is approximately −10 mm Hg during inspiration and −2 mm Hg during expiration. Intrapleural pressures are similarly negative during inspiration but rise to slightly positive during expiration. This largely negative intrapleural force maintains lung expansion and promotes venous return to the heart, which is greater during inspiration.

67.3. Which of the following may differentiate spontaneous pneumomediastinum from spontaneous pneumothorax?
A. Cough
B. Occurrence during exertion
C. Pain
D. Tachycardia
E. Tachypnea

Answer: B. Spontaneous pneumomediastinum, unlike pneumothorax, often occurs with exertion, particularly after a strenuous Valsalva maneuver. Signs and symptoms—pain, cough, tachycardia, and tachypnea—are similar in the two conditions.

67.4. A 29-year-old, otherwise healthy man presents with acute onset of right pleuritic chest pain and modest cough. The symptoms occurred at rest. Physical examination is remarkable only for a tachycardia of 108 beats/min. Chest radiography reveals an estimated 30% right pneumothorax. Review of symptoms and past history are negative. Which of the following would be suitable management?
A. Admission for 100% face mask oxygen and repeat radiography in 1 day
B. Endotracheal intubation
C. One-time air aspiration and repeat radiography in 6 hours
D. Reassurance and observation
E. Tube thoracostomy

Answer: C. Observation is typically indicated for primary spontaneous pneumothoraces less than 20%. Larger primary spontaneous cases may be treated with aspiration and repeat chest radiography. Advantages include lower cost and morbidity and lack of invasiveness. Success rates range from 45% to 71%. Tube thoracostomy is indicated for most cases of secondary spontaneous pneumothorax and if any pleural fluid is present.

67.5. Which of the following statements is true regarding the routine application of suction after tube thoracostomy?
A. It improves the rate of lung expansion.
B. It increases the risk of reexpansion pulmonary edema.
C. It is associated with increased rates of empyema.
D. It is not routinely indicated.
E. When indicated, it should be applied with a pressure of at least 10 cm H2O.

Answer: D. Suction neither accelerates lung reexpansion nor improves outcomes. It is indicated when reexpansion with a Heimlich or water seal device does not occur after 24 to 48 hours. A pressure of at least 20 cm H2O should be used.

67.6. A 68-year-old man with a history of esophageal cancer presents with progressive fever, chest pain, and shortness
of breath over 24 hours. Chest radiography demonstrates a possible left lower lobe pneumonia and large left pleural effusion. Pleural fluid analysis reveals pH of 6.95, glucose level of 47 mg/dL, 11,500 white blood cells (WBCs)/mm³ (82% neutrophils), and protein level 75% of plasma levels. What are the indicated next steps in management?

A. Antibiotics and fluid resuscitation
B. Antibiotics and tube thoracostomy
C. Antibiotics, tube thoracostomy, and esophageal Gastrografin study
D. One-time pleural aspiration for fluid analysis
E. Pleural Gram staining and culture and tube thoracostomy if infection is confirmed

Answer: C. This is an exudative pleural effusion as defined by Light’s criteria (see Box 67.3). A pH less than 7.0 suggests emphysema or esophageal rupture. This patient is at risk for both; hence, the need to assess esophageal integrity. A pH less than 7.0 with glucose level less than 50 mg/dL are indications for tube thoracostomy. Normal pleural fluid has a WBC count of less than 1,000/mm³.
Acute coronary syndrome (ACS) refers to the constellation of clinical diseases occurring as a result of acute myocardial ischemia. ACS includes a spectrum of clinical presentations ranging from unstable angina (UA) to acute myocardial infarction (AMI), including two AMI subtypes, non–ST segment elevation myocardial infarction (NSTEMI) and ST segment elevation myocardial infarction (STEMI). Sudden cardiac death (SCD) is the most extreme form of ACS. ACS, particularly AMI and its sequelae, remain the leading causes of death in much of the developed world.

Several advances in the mid-20th century have drastically changed the approach to acute coronary care. The first developments of significance—external defibrillators, cardiac pacemakers, and new pharmacologic agents—have provided emergency clinicians with effective approaches for treating life-threatening dysrhythmias occurring as a result of AMI. The introduction of selective coronary arteriography by Sones revolutionized the management of patients with coronary artery disease (CAD). In 1960, Kouwenhoven inaugurated the era of cardiopulmonary resuscitation (CPR), providing an important tool in the management of SCD.

These developments led to the recognition that the time between onset of symptoms and initiation of therapy is critical. Management priorities were directed at complications of AMI. Day organized a cardiac arrest team in 1960 and established the first coronary care unit 2 years later, reducing AMI mortality by half. In the 1980s, DeWood performed coronary angiography early in the course of AMI and demonstrated coronary occlusion in the infarct-related artery. Later in that decade, the experience of Rentrop with the intracoronary administration of streptokinase for AMI ushered in the era of thrombolysis, now termed fibrinolytic therapy. This accomplishment, the use of fibrinolytic therapy, allowed the emergency clinician to interrupt the actual infarction, restoring perfusion to the infarct-related artery and anatomic segment that were experiencing AMI. Acute cardiac care was then revolutionized, and the reperfusion era was born.

Recognition that most sudden deaths from ischemic heart disease occur outside the hospital led to numerous advances for prehospital ACS care. In 1969, advanced prehospital cardiac care was initiated in Belfast with Pantridge’s mobile cardiac care units. In 1970, Nagel reported the benefits of prehospital telemetry for field providers of advanced cardiac life support in patients experiencing dysrhythmias or sudden cardiac death. In the 1980s, portable 12-lead electrocardiograms (ECGs) were introduced into the emergency medical services (EMS) environment, enabling the diagnosis of STEMI prior to hospital arrival.

Fibrinolytic therapy and interventional, catheter-based techniques revolutionized the treatment of patients with STEMI during the late 1980s. Combination therapies with antiplatelet, antithrombotic, and fibrinolytic agents continue to be studied for STEMI patients, further optimizing reperfusion and adjunctive therapies. Interventional success has been improving with the use of newer stenting devices and various platelet and coagulation system inhibitors. STEMI systems of care address the management of STEMI from a systems-based perspective, starting with EMS in the prehospital setting through the emergency department (ED) to the cardiac catheterization laboratory (CCL) and coronary care unit. This systems-based approach stresses a number of factors crucial in the management of STEMI, including the time sensitivity of treatment, a multidisciplinary composition of the management team, and multistep nature of the overall process. In addition to further development of the STEMI systems of care approach, current efforts focus on the establishment of regional cardiac centers and expansion of interventional capabilities to smaller hospitals. Furthermore, appropriate methods of evaluation of potential ACS patients without obvious STEMI or other diagnostic findings continue to mature. The observation unit–based rule-out myocardial infarction (MI) strategy has been shortened in total time, rendered more efficient in process, and made safer with respect to medical management and detection of ACS events. Although this strategy of chest pain evaluation is more efficient than previous approaches, further improvements in reducing the missed MI in the ED are under development.

**EPIDEMIOLOGY**

Ischemic heart disease and CAD, the immediate effects and sequelae, continue to be the leading causes of death among adults in many developed countries, including the United States and Canada. Ischemic heart disease accounts for nearly 1 million deaths in the United States annually, of which approximately 160,000 occur in persons 65 years of age or younger. More than half of all deaths from cardiovascular disease occur in women, and CAD remains a major cause of morbidity and mortality in women beyond their middle to late 50s. The incidence of cardiovascular disease is expected to continue to increase owing to lifestyle and behavioral changes that promote heart disease.

A significant reduction in age-adjusted mortality from CAD has occurred in the United States and Canada over the past 5 decades; this decline continues while the incidence of ACS is increasing. In large part, the decline has been accompanied by diminished mortality from AMI. This decrease is a result of a reduction in the incidence of AMI by 25% and a sharp drop in the case-fatality rate. Reduction in cigarette smoking, management of lipids, and improved management of hypertension and diabetes mellitus undoubtedly play a role, along with significant advances in medical treatment.
In 2005, 5.8 million patients were evaluated for chest pain or related complaints in EDs in the United States, constituting 5% of all ED visits. In 2004, 4.1 million visits to the ED had a primary diagnosis of cardiovascular disease, and over 1.5 million patients were hospitalized for a primary or secondary diagnosis of ACS. In addition, approximately 2% of patients with ACS are inappropriately discharged from the ED. In the United States, approximately 900,000 persons experience an AMI every year, of whom 20% die before reaching the hospital, and 30% die within 30 days. The majority of fatalities from CAD occur outside the hospital, usually from an ACS-related dysrhythmia within 2 hours of onset of symptoms. For many patients who experience a nonfatal AMI, their lives are limited by impaired functional status, anginal symptoms, and diminished quality of life. The economic cost of ACS is estimated to be $120 to $140 billion annually.

Spectrum of Illness: Coronary Artery Disease and Acute Coronary Syndrome

Coronary heart disease includes the spectrum from asymptomatic CAD and stable angina to UA, AMI, and sudden cardiac death. ACS includes the acute subtypes of coronary heart disease, including UA, AMI, and sudden cardiac death; AMI is further subdivided into NSTEMI and STEMI.

Stable Angina

Stable angina pectoris, not considered a form of ACS, is transient, episodic chest discomfort resulting from myocardial ischemia. This discomfort is typically predictable and reproducible, with the frequency of attacks constant over time. Physical or psychological stress (eg, physical exertion, emotional stress, anemia, dysrhythmias, environmental exposures) may provoke an attack of angina that resolves spontaneously over a constant, predictable period of time with rest or nitroglycerin (NTG).

The Canadian Cardiovascular Society (CCS) classification for angina is defined as follows:

- Class I—no angina with ordinary physical activity
- Class II—minimal limitation of normal activity as angina occurs with exertion or emotional stress
- Class III—severe limitation of ordinary physical activity as angina occurs with exertion under normal physical conditions
- Class IV—inability to perform any physical activity without discomfort as anginal symptoms occur at rest or with minimal physical exertion

Unstable Angina

Unstable angina should be considered from a semantic perspective and pathophysiologic perspective; when considered together, unstable angina is best defined from its description as well as the results of the clinical evaluation. From the semantic perspective, unstable angina is broadly defined as angina that is new onset or occurring at rest or with minimal exertion. It is further defined as angina that is worsening from a previously stable pattern of pain occurrence in terms of frequency or duration of attacks, resistance to previously effective medications, or provocation with decreasing levels of exertion or stress.

Rest angina is defined as angina occurring at rest, lasting longer than 20 minutes, and occurring within 1 week of presentation. New-onset angina is angina of at least CCS classification class II severity, with onset within the previous 2 months. Increasing or progressive angina is diagnosed when a previously known angina becomes more frequent, longer in duration, or increased by one class within the previous 2 months of at least class III severity.

Symptoms that last longer than 20 minutes, despite cessation of activity, are consistent with angina at rest; in the appropriate clinical setting, such a presentation could be considered UA.

UA is often referred to as preinfarction angina, accelerating or crescendo angina, intermediate coronary syndrome, and preocclusive syndrome, underscoring its difference from stable angina. In its more severe forms, UA should be considered a possible harbinger of AMI and, hence, should be treated aggressively.

UA can also be defined from a pathophysiologic perspective. Plaque rupture accompanied by thrombus formation and vasoconstriction illustrate the intracoronary events of UA. This is frequently characterized by an electrocardiographic abnormality, including T wave and ST segment changes.

Variant angina—also known as Prinzmetal’s angina—is caused by coronary artery vasospasm at rest with minimal fixed coronary artery lesions; it may be relieved by exercise or NTG. The ECG reveals ST segment elevation that is impossible to discern from STEMI clinically and electrocardiographically.

Acute Myocardial Infarction

Acute myocardial infarction is defined as myocardial cell death with necrosis of the myocardium. The 4-decade-old World Health Organization (WHO) definition for AMI has been replaced by clinical criteria developed jointly by the European Society for Cardiology and American College of Cardiology (ACC) that focus on defining infarction as any evidence of myocardial necrosis. This definition for an acute, evolving, or recent MI requires a typical rise and fall of a cardiac biochemical marker, currently troponin, with clinical symptoms, electrocardiographic changes, or coronary artery abnormalities based on interventional evaluation. The actual definition, referred to as the universal definition of myocardial infarction, includes the following; either one of these criteria satisfies the diagnosis for an acute, evolving, or recent MI:

1. Typical rise and gradual fall or more rapid rise and fall of biochemical markers of myocardial necrosis, with at least one value above the 99th percentile of the upper reference limit (URL) and with at least one of the following clinical parameters:
   - Ischemic symptoms
   - Electrocardiographic changes indicative of ischemia (T wave changes or ST segment deviation
   - Development of pathologic Q waves on the ECG and/or
   - Imaging evidence of presumably new findings, such as a loss of viable myocardium or a regional wall motion abnormality

2. Pathologic findings of an AMI

Furthermore, regarding an established MI, any one of the following criteria satisfies this diagnosis:

- Development of new pathologic Q waves on serial ECGs. The patient may or may not remember previous symptoms; biochemical markers of myocardial necrosis may have normalized, depending on the length of time since the infarct developed.
- Imaging study findings consistent with MI—imaging evidence of a region of loss of viable myocardium that is thinned and fails to contract in the absence of a nonischemic cause
- Pathologic findings of a healed or healing MI

Considering the myriad clinical situations in which AMI is encountered, the five primary types of infarction are described by the following classification:

Type 1—spontaneous MI related to ischemia resulting from a primary coronary event, such as plaque erosion rupture, erosion, fissuring, or dissection with accompanying thrombus
formation and vasospasm. Type 1 infarctions represent the true ACS event.

Type 2—MI secondary to ischemia caused by increased oxygen demand or decreased supply, as seen in coronary artery spasm, coronary embolism, severe anemia, compromising arrhythmias, or significant systemic hypotension related to a range of causes.

Type 3—sudden unexpected cardiac death, including cardiac arrest, often with symptoms suggestive of myocardial ischemia, accompanied by presumably new ST segment elevation or new left bundle branch block (LBBB) pattern. Fresh coronary thrombus is noted via angiography or autopsy; death occurs before appropriate sampling of the blood to detect the abnormal cardiac biomarker.

Type 4—MI associated with coronary instrumentation, such as occurring after percutaneous coronary intervention (PCI). For PCIs in patients with normal baseline troponin values, elevations of cardiac biomarkers above the 99th percentile URL are indicative of periprocedural myocardial necrosis. By convention, increases of biomarkers greater than three times the 99th percentile URL are designated as defining PCI-related MI. A subtype related to a documented stent thrombosis is similarly recognized.

Type 5—MI associated with coronary artery bypass grafting (CABG). For CABG in patients with normal baseline troponin values, elevations of cardiac biomarkers above the 99th percentile URL are indicative of periprocedural myocardial necrosis. By convention, increases of biomarkers greater than five times the 99th percentile URL, plus any of the following, are designated as defining CABG-related MI:
- New pathologic Q waves or new LLLB
- Angiographically documented new graft or native coronary artery occlusion
- Imaging evidence of new loss of viable myocardium

This categorization is more than a simple semantic description of AMI. Diagnostic and management issues clearly are different, depending on the subtype of MI encountered. For example, the type 1 event should be approached with attention to platelet, coagulation system, and vasospasm considerations, whereas the type 2 infarction should have attention paid to the inciting pathophysiologic situation causing imbalance in oxygen delivery and myocyte requirements.

AMI is further classified by findings on the ECG and serum markers at presentation as NSTEMI or STEMI. Previous descriptors, such as transmural, nontransmural, Q wave, and non-Q wave MI fail to describe the coronary event and its related pathophysiology, electrocardiographic presentation, and pathologic outcome adequately. The differentiation between STEMI and NSTEMI has important implications in terms of management, outcome, and prognosis for patients with AMI. In fact, the ACC and American Heart Association (AHA) have separate clinical guidelines for the management of patients with UA-NSTEMI and those with STEMI.22

**PATHOPHYSIOLOGY**

The underlying pathophysiology of ACS is myocardial ischemia as a result of inadequate perfusion to meet myocardial oxygen demand. Myocardial oxygen consumption is determined by heart rate, afterload, contractility, and wall tension. Inadequate perfusion usually results from coronary arterial vessel stenosis as a result of atherosclerotic CAD. Usually, the reduction of coronary blood flow does not cause ischemic symptoms at rest until the vessel stenosis exceeds 95% obstruction to flow. Myocardial ischemia, however, may occur with exercise and increased myocardial oxygen consumption with as little as 60% vessel stenosis.

CAD is characterized by thickening and obstruction of the coronary vessel arterial lumen by atherosclerotic plaques. Although atherosclerosis is usually diffuse and multifocal, individual plaques vary greatly in composition. Fibrous plaques are considered stable but can produce anginal symptoms with exercise and increased myocardial oxygen consumption because of the reduction in coronary artery blood flow through the fixed stenotic lesions. Vulnerable, or unstable, fibrolipid plaques consist of a lipid-rich core separated from the arterial lumen by a fibromuscular cap. These lesions are likely to rupture, resulting in a cascade of inflammatory events, thrombus formation, and platelet aggregation that can cause acute obstruction of the arterial lumen and myocardial necrosis; this rupture initiates the pathophysiologic process of ACS.

Thrombus formation is considered an integral factor in ACS, including all subtypes ranging from UA to AMI. These syndromes are initiated by endothelial damage and atherosclerotic plaque disruption, which leads to platelet activation and thrombus formation. Platelets play a major role in the thrombotic response to rupture of coronary artery plaque and subsequent ACS. Platelet-rich thrombi are also more resistant to fibrinolysis than fibrin- and erythrocyte-rich thrombi. The resulting thrombus can occlude the vessel lumen, leading to myocardial ischemia, hypoxia, acidosis, and eventually infarction. The consequences of the occlusion depend on the extent of the thrombotic process, characteristics of the preexisting plaque, extent of the vessel obstruction, and availability of collateral circulation.

In the setting of UA, acute stenosis of the vessel is noted; complete obstruction, however, is encountered in only 20% of cases. In these cases, it is likely that extensive collateral vessel circulation prevents total cessation of blood flow, averting frank infarction.5 With AMI, the occlusive, fibrin-rich thrombus is fixed and persistent, resulting in myonecrosis of the cardiac tissue supplied by the affected artery. Angiographic studies have demonstrated that the preceding coronary plaque lesion is often less than 50% stenotic, indicating that the most important factors in the infarction are the acute events of plaque rupture, platelet activation, and thrombus formation rather than the severity of the underlying coronary artery stenosis.

Another important aspect of ACS is vasospasm. After significant coronary vessel occlusion, local mediators and vasoactive substances are released, inducing vasospasm, which further compromises blood flow. Central and sympathetic nervous system input increases within minutes of the occlusion, resulting in vasomotor hyperreactivity and coronary vasospasm. Sympathetic stimulation by endogenous hormones, such as epinephrine and serotonin, may also result in increased platelet aggregation and neutrophil-mediated vasconstriction. Approximately 10% of MIs occur as a result of coronary artery spasm and subsequent thrombus formation without significant underlying CAD. This mechanism may be more prevalent during UA and other coronary syndromes that do not result in infarction.

Further myocardial injury occurs at the cellular level as inflammatory, thrombotic, and other debris from the occlusive plaque lesion is released and embolizes into the distal vessel. Such embolization can result in obstruction at the microvasculature, leading to hypoperfusion and ischemia of the distal myocardial tissue, even after reopening of the more proximal, initial obstructing lesion. In particular, the introduction of calcium, oxygen, and cellular elements into ischemic myocardium can lead to irreversible myocardial damage that causes reperfusion injury, prolonged ventricular dysfunction (known as myocardial stunning), or reperfusion dysrhythmias. Neutrophils probably play an important role in reperfusion injury, occluding capillary lumens, decreasing blood flow, accelerating the inflammatory response, and resulting in the production of chemoattractants, proteolytic enzymes, and reactive oxygen species.
Clinical features associated with ACS vary based on the patient type, including gender, comorbid conditions, and age considerations. Women, patients with diabetes mellitus, and older adults, among other populations, can exhibit differing presentations of ACS. Women can demonstrate less remarkable ACS presentations. Diabetic patients frequently exhibit nontraditional symptoms of ACS, such as dyspnea. Older adults commonly note only weakness, confusion, or other nonclassic symptoms as the primary manifestation of ACS.

Prehospital Evaluation

Appropriate pharmacotherapy for suspected ACS in the prehospital setting includes sublingual NTG, oral aspirin (acetylsalicylic acid [ASA]) that is preferably chewed, and intravenous (IV) opioid analgesic agents, such as morphine sulfate or fentanyl. Of these three agents, only ASA is associated with a documented improvement in outcome related to AMI; NTG and opioid analgesics can reduce chest discomfort, dyspnea, and anxiety associated with the current situation, although neither class of medications has been demonstrated to improve outcome in the ACS patient. Thus, their administration is not mandatory nor required in any fashion.

Establishment of the diagnosis of ACS in this setting is difficult, however, because chest pain is a poor predictor of the diagnosis of AMI, and adjunctive tools are limited. A prehospital 12-lead ECG offers high specificity (99%) and positive predictive value (93%) for STEMI in patients with atraumatic chest pain while increasing the paramedic scene time by an average of only 3 minutes. This approach offers many advantages, including the following: (1) earlier detection of STEMI; (2) ability to base the destination on the availability of PCI; (3) hospital-based preparation for patient arrival; and (4) more rapid initiation of hospital-based reperfusion therapy, either fibrinolysis or PCI.

Emergency Department Evaluation

History

The character of the chest discomfort, as well as the onset, location, radiation, duration, prior presence, and any exacerbating or alleviating factors, should be sought. Associated symptoms, especially of a cardiac, pulmonary, gastrointestinal, and/or neurologic nature, should be elicited. Results from any prior cardiac testing should be obtained, if logistically and practically possible.

Traditionally, a history of risk factors for CAD is sought; these include male gender, age, tobacco smoking, hypertension, diabetes mellitus, hyperlipidemia, and family history of AMI at an early age (usually <50 years); additional risk factors to consider include artificial or early menopause and chronic cocaine abuse. Approximately 80% of a population of more than 122,000 patients with known CAD had at least one of the four conventional risk factors—diabetes mellitus, cigarette smoking, hypertension, or hyperlipidemia. However, cardiac risk factor burden has little impact on the ED diagnosis of ACS but, in older patients, ACS is significantly more likely if four of the five major risk factors—diabetes mellitus, smoking, hypertension, hyperlipidemia, and family history—are present (compared with none). Nevertheless, Bayesian analysis indicates that risk factors are a population phenomenon and do not increase or decrease the likelihood of any condition in any one patient. Thus, the presence of an individual risk factor or collection of risk factors is far less important in diagnosing ACS in the ED than the history of presenting illness, prior diagnosis of ischemic cardiac disease in the patient, presence of ST segment or T wave changes, or cardiac marker abnormalities, or all these clinical features considered as a whole.

Risk assessment tools, such as the PURSUIT (Platelet Glycoprotein IIb-IIIa in Unstable Angina: Receptor Suppression Using Integrilin Therapy) risk model, GRACE (Global Registry of Acute Coronary Events) risk model, and TIMI (Thrombolysis in Myocardial Infarction) risk score, can be used to determine the risk of death and ischemia in NSTEMI and STEMI. However, these and similar clinical decision tools should not be used solely to determine disposition from the ED.

The TIMI risk score assigns a point each for seven factors based on history, cardiac markers, and ECG (it can be accessed at www.timi.org). Although these tools may aid in decision making and risk stratification for patients to determine their inpatient disposition properly (telemetry bed vs. intensive care unit), none of them, when used as the sole determinant, are designed to identify patients who may safely be discharged home. Recent investigations of the TIMI risk score in the ED has confirmed that it can be used as one of several consideration to assist in determining disposition in ED patients; yet, again, it should not be used as the sole means of this determination.

There are several nontraditional risk factors for coronary disease that should be considered in the appropriate patient. Antiphospholipid syndrome, rheumatoid arthritis, human immunodeficiency virus (HIV), and particularly systemic lupus erythematosus (SLE) are associated with a higher risk of cardiovascular disease. Women with SLE who are 35 to 44 years of age are more than 50 times more likely to have an MI than a similar age- and gender-matched Framingham population.

Classic History. The term angina refers to tightening, not pain. Classic angina pectoris may not be pain at all but rather described as a discomfort, with a squeezing, pressure, tightness, fullness, heaviness, or burning sensation. Classically, it is substernal or precordial in location and may radiate to the neck, jaw, shoulders, or arms. If the discomfort does extend down the arm, it typically involves the ulnar aspect. Discomfort in the left chest and radiation to left-sided structures is usual, but location and radiation to both sides or only to the right side can be consistent with angina. Radiation of the discomfort to the right arm or shoulder, or to both arms or shoulders, are also presentations of ACS and are consistent with the diagnosis. Refer to Table 68.1 for characteristics of angina chest pain.

Adapted from Zink BJ: Angina and unstable angina. In Gibler WB, Aufderheide TP, editors: Emergency cardiac care, St. Louis, 1994, Mosby.
Symptoms characteristically associated with angina pectoris, or other entities of ACS, include dyspnea, nausea, vomiting, diaphoresis, weakness, dizziness, excessive fatigue, and anxiety. These symptoms can be considered as associated symptoms and anginal equivalent symptoms. If these symptoms arise without chest discomfort, alone or in combination, as a presenting pattern of known ischemic coronary disease, they are termed anginal equivalent symptoms. Recognition that coronary ischemia may arise with an anginal equivalent rather than a classic symptom is the key to understanding the atypical presentation of ACS. Dyspnea is the most common angina equivalent symptom presentation. Isolated diaphoresis, nausea, and emesis are very uncommon sole presenting symptoms in ACS; weakness, dizziness, excessive fatigue, and anxiety likely do not occur as the single presenting complaint, or manifestation, in the ACS patient except, perhaps in the extreme older patient population.

If there are complaints of gas, indigestion, or heartburn in the absence of a known history of gastroesophageal reflux disease, the heartburn is different from the patient’s usual gastroesophageal reflux, or there is a lack of reproducible pain on abdominal palpation, this should raise suspicion of ACS. However, these presenting complaints do not indicate ACS in most cases. Nonetheless, gastroesophageal and upper gastrointestinal (GI) maladies are common misdiagnoses in cases of missed AMI.

Nontraditional (or Atypical) History. A description of typical symptoms is at times lacking in ACS; this nontraditional presentation may be a result of atypical features of the pain (eg, character, location, duration, exacerbating and alleviating factors) or the presence of anginal equivalent symptoms (eg, dyspnea). Patients with an ultimate diagnosis of ACS can have pain that is pleuritic, positional, or reproduced by palpation. Some patients describe their pain as burning or indigestion, sharp, or stabbing. Of course, a single historical point or combination of points does not rule in nor rule out ACS. Rather, the emergency clinician evaluating the patient must consider the chief and related complaints as well as the other features of the presentation—in other words, the entire diagnostic picture.

Previous studies have shown that of the ED patients ultimately diagnosed with AMI, one-third did not have chest pain on presentation. Multiple studies have identified risk factors for an atypical presentation of ACS, including diabetes mellitus, older age, female gender, nonwhite ethnicity, dementia, no prior history of MI or hypercholesterolemia, no family history of coronary disease, and previous history of congestive heart failure (CHF) or stroke. Atypical features of ACS are present with increasing frequency in sequentially older populations. Before age 85, chest pain is found in most patients with AMI, although dyspnea, stroke, weakness, and altered mental status are notably present. In those older than 85 years, however, atypical symptoms are more common than chest pain, with 60% to 70% of patients older than 85 years having an anginal equivalent complaint, especially dyspnea. Coincident ACS is more likely to occur in older adults; patients with another acute condition (eg, trauma, infection) should be scrutinized for concurrent ACS.

Patients with diabetes mellitus are at heightened risk for ACS and an atypical presentation. Medically unrecognized AMI can occur in 40% of patients with diabetes mellitus compared with 25% of a nondiabetic population, and a myocardial scar unaccompanied by an antemortem diagnosis of MI is three times more likely in diabetics. As with age and diabetes, female gender is an important risk factor for AMI without a classic chest pain presentation. In some series, less than 60% of women reported typical chest discomfort at the time of their AMI, with others reporting dyspnea, indigestion, or vague symptoms, such as weakness, unusual fatigue, cold sweats, sleep disturbance, anxiety, and dizziness.

Finally, nonwhite racial and ethnic populations may have atypical symptoms in ACS. Compelling data have demonstrated a disparity in treatment approach related to race and ethnicity in patients with acute manifestations of coronary heart disease. Whether this is related to the atypical nature of presenting symptoms in different racial and ethnic groups is not clear. Although certain features of the chest pain history serve to increase or decrease the likelihood of ACS, none of them is strong enough to endorse discharge of the patient based on the history alone.

Outcomes in Nontraditional Presentations

Not surprisingly, atypical presentation of patients with ACS is associated with poorer outcomes; this worsened outcome is a function of a prolongation in the time to ACS treatment and, unfortunately, is understandable. If the diagnosis is not suspected, appropriate treatment cannot be started. It has been demonstrated that patients with an AMI without chest pain were significantly more likely to die in the hospital (two- to threefold increased mortality when compared to patients with chest pain) and were more likely to experience stroke, hypotension, or heart failure that required intervention, possibly reflecting the older age and greater comorbidity in this group. Patients with atypical symptomatology seek medical care later and are less likely to receive appropriate treatment. Patients 65 years of age or younger with NSTEMI have a 1% chance of dying during their hospitalization, but this risk is increased to 10% for patients aged 85 years and older.

Physical Examination

The physical examination focuses on the cardiac, pulmonary, abdominal, and neurologic examinations, looking for complications of ACS as well as alternative diagnoses for chest pain (Table 68.2). In general, the physical examination in the ACS patient will demonstrate few findings suggestive of ACS; pale appearance, anxiety, and diaphoresis are frequent findings in patients with severe forms of UA and AMI. Bradycardia, tachycardia, hypotension, and pulmonary edema, not infrequent in the AMI patient, are manifestations of ACS complication; these findings also are ominous signs in patients with known or suspected ACS.

Historical studies, using untrained physicians (ie, not emergency clinicians), identified chest wall tenderness or reproducible chest wall tenderness in up to 15% of patients ultimately diagnosed with AMI, but these data are highly suspect. The real

CHAPTER 68 Acute Coronary Syndrome
Missed Diagnosis of Acute Coronary Syndrome

Approximately 2% to 4% of patients with AMI in the ED are discharged without diagnosis. Missed ACS is the misdiagnosis that accounts for the largest amount of payments by emergency clinicians in medical malpractice claims. Atypical presenting symptoms are an obvious causative consideration. Patients with undiagnosed ACS discharged from the ED are younger, more likely to be women or nonwhite, more likely to have atypical complaints, and less likely to have electrocardiographic evidence of acute ischemia. Among all patients with cardiac ischemia, women younger than 55 years seem to be at highest risk for inappropriate discharge. With respect to electrocardiographic findings, it has been shown that 53% of patients with missed AMI and 62% of patients with missed UA have normal or nondiagnostic ECGs. Finally, the risk-adjusted mortality ratio for all patients with acute cardiac ischemia is 1.9 times higher among nonhospitalized patients. Factors associated with misdiagnosis of ACS in medical malpractice closed claims analysis include emergency clinicians with less experience who document histories less clearly, admit fewer patients, and misinterpret the ECG.

Early Complications of Acute Myocardial Infarction

Bradydysrhythmia and atrioventricular (AV) conduction block occur in 25% to 30% of patients with AMI; sinus bradycardia is usually seen. Symptomatic bradydysrhythmias in the first few hours after inferior STEMI tend to be atropine-responsive; conduction abnormalities that appear beyond 24 hours of AMI tend not to respond to atropine. Patients with AV block in the setting of anterior STEMI tend to respond poorly to therapy and have a poor prognosis.

Tachydysrhythmias are common in the setting of AMI and may be atrial in origin (eg, sinus tachycardia and atrial fibrillation) or ventricular (eg, ventricular tachycardia and fibrillation). Not all require treatment, such as a compensatory sinus tachycardia in patients with AMI complicated by CHF. Primary ventricular fibrillation occurs in an estimated 4% to 5% of patients with AMI, with 60% of those cases occurring in the first 4 hours and 80% within 12 hours.

Cardiogenic shock is defined as hypotension with end-organ hypoperfusion resulting from decreased cardiac output unresponsive to restoration of adequate preload. Patients at risk include those with large infarctions, prior MI, low ejection fraction on presentation (<35%), older age, and diabetes mellitus. Adjunctive diagnostic measures include bedside echocardiography and invasive hemodynamic monitoring, with the latter demonstrating systemic hypotension, low cardiac output, elevated filling pressures, and increased systemic vascular resistance. Therapeutic measures include vasopressor and inotropic support, intraaortic balloon counterpulsation, and early revascularization; fibrinolytic therapy does not decrease mortality in cardiogenic shock.

Left ventricular free wall rupture is uncommon. Approximately one-third of cases occur in the first 24 hours, and the remainder occur 3 to 5 days after large MIs, typically anterior wall STEMI. Clinically, free wall rupture may occur with sudden death, pulseless electrical activity, or precipitous deterioration in the presence of STEMI. Signs of pericardial effusion on the ECG or echocardiogram are suggestive of the diagnosis in the setting of an acute or recent MI. This diagnosis is significantly challenging and difficult to establish. Free wall rupture is almost universally fatal, although prompt diagnosis followed by emergent surgical intervention may rarely be lifesaving; pericardiocentesis is indicated as an immediate temporizing intervention if the diagnosis is suspected.

Rupture of the interventricular septum may also occur; regarding the time of presentation and AMI type, rupture of the interventricular septum is similar to that of rupture of the free wall of the left ventricle. The clue to this diagnosis on physical examination is the development of a new, harsh, loud holosystolic murmur heard best at the left lower sternal border. The diagnosis can be confirmed by echocardiography with color flow Doppler imaging. The presentation of acute catastrophic deterioration with a new, harsh systolic murmur should prompt immediate cardiac surgery consultation for repair of a septal defect or ruptured papillary muscle of the mitral valve. Medical therapy, including vasopressor and inotropic support, as well as intraaortic balloon counterpulsation, is an important bridge to the definitive surgical treatments of valve repair or replacement. As with free wall rupture, this diagnosis is significantly challenging and difficult to establish.

Pericarditis, when associated with AMI, can occur early or in a delayed fashion; the former is termed *infarct-related pericarditis*, and the latter is known as post-MI or Dressler’s syndrome. Infarct-related, or infarct, pericarditis is associated with transmural insult and thus principally involves the pinnacle of the infarct zone near the epicardium. Although the characteristic ST segment changes may be obscured by ST segment abnormalities related to the infarction itself, they are localized if they are evident. Infarct pericarditis is a common cause of new chest pain in the first week after MI. This pain is characteristically pleuritic and worse in the supine position, likely quite different from the chest discomfort experienced resulting from the AMI. Embolic complications are more common in patients with infarct pericarditis; linked to this is the higher rate of ventricular aneurysm development in this population.

Dressler’s syndrome, unlike infarct pericarditis, does not require transmural involvement. It is a relatively uncommon late complication occurring from 1 to several months after the MI. Clinical features include fever, malaise, pleuroperticardial pain and, at times, the presence of a rub on cardiac auscultation. Laboratory findings are highly nonspecific and include an elevated erythrocyte sedimentation rate and leukocyte count. The ECG may show ST segment–T wave findings of pericarditis although, as with infarct pericarditis, these changes may be overshadowed by the evolving changes of the recent MI. PR segment depression is a telltale clue. Pericardial or pleural effusions may be evident and can be serous or bloody. Echocardiography assesses pericardial fluid and risk of tamponade. The pericardial reaction is believed to be immune-mediated; treatment includes antiinflammatory agents.

Stroke may also complicate AMI, usually ischemic or thromboembolic. The major predisposing mechanisms with a recent MI are embolization from a left ventricular mural thrombus with decreased ejection fraction, embolization from the left atrial appendage with atrial fibrillation, and hypercoagulability with concomitant carotid arterial disease. It is known that the rate of stroke is higher in the setting of MI (0.9%, tapering to 0.1% at day 28 after MI) than in similar non-AMI patients (0.014%).

Hemorrhagic stroke is an obvious concern in the patient undergoing fibrinolytic therapy. The rate of hemorrhagic stroke with varying fibrinolytic agents is less than 1%; the rate is marginally higher in older patients. PCI lowers the overall risk of stroke compared with fibrinolytic therapy. Analysis of only fibrinolytic-eligible patients from the NRMI-2 database indicates more than 24,000 patients treated with alteplase and more than 4000 who
received primary PCI (termed "angioplasty" in this study). The difference in stroke rate is highly significant (1.6% in the fibrinolytic group vs. 0.7% in the PCI group). Considering hemorrhagic strokes, we have seen that the difference is again dramatic (1.0% in the fibrinolytic group vs. 0.1% in the PCI group).

Adverse events of ACS therapy should also be considered as potential complications, including hemorrhage associated with medications resulting from invasive procedures. The various antiplatelet, anticoagulant, and fibrinolytic therapies (as noted earlier) are all associated with hemorrhage as a major complicating issue. Within a single class of medications, many of these agents are so similar in efficacy that superiority is determined by the rate of occurrence of adverse effects; this trend in an adverse reaction profile with anticoagulant-antiplatelet medication is most important to understand for agent selection. Aggressive supportive care coupled with so-called antidote therapy is the most appropriate approach to patients with hemorrhagic complications from medication. Protamine can be helpful in the reversal of the heparins. Fresh-frozen plasma (FFP) and platelet infusions are of value in certain anticoagulant and antiplatelet scenarios. The low-molecular-weight heparins (LMWHs) cannot be reversed. Fibrinolytic agents also cannot be reversed; rather, therapy including FFP and packed red blood cell transfusions is most appropriate. These various antidotal agents should be considered only with life-threatening hemorrhage. The emergency clinician at the bedside, who can evaluate the risks and benefits of these treatments in the setting of a complicated ACS event, is in the best position to determine management strategies.

Procedural complications include arterial injury with hemorrhage related to percutaneous interventions; the most typical is a pseudoaneurysm of the femoral artery with hemorrhage into the thigh compartment or retroperitoneal area. The diagnosis is made based on a high degree of clinical suspicion in a patient with recent femoral artery cannulization. Physical examination findings, including extensive bruising in the thigh and bruits over the femoral artery, are suggestive; ultrasonography or CT of the thigh or retroperitoneal area can confirm the diagnosis.

**DIAGNOSTIC CONSIDERATIONS**

**Differential Diagnoses**

The differential diagnosis of chest pain in the adult patient is broad and includes life-threatening and non–life-threatening causes. The nontraumatic potential life threats include AMI, unstable angina, aortic dissection, aortic aneurysm with perforation, pulmonary embolus, spontaneous pneumothorax, esophageal perforation, myopericarditis, and pneumonia; traumatic life threats include pulmonary contusion or laceration, traumatic pneumothorax, and penetrating chest wounds. Non–life-threatening causes are numerous and include costochondritis, musculoskeletal chest pain, herpes zoster infection, and various gastrointestinal maladies; although these entities are usually non–life-threatening, significant morbidity can occur (Tables 68.2 and 68.3)

**Diagnostic Testing**

**Electrocardiography**

In the patient with chest discomfort or other symptoms suggestive of ACS, the 12-lead ECG can assist in a number of important applications, including establishing the diagnosis, determining candidacy for various therapies, and performing risk assessment. In the setting of STEMI, the ECG provides crucial data regarding the diagnosis—anatomically arrayed ST segment elevation of at least 1 to 2 mV in at least two leads. Furthermore, the ECG provides pivotal information regarding therapeutic intervention; ST segment elevation establishes candidacy for emergent reperfusion therapy, fibrinolysis or PCI. Regarding risk assessment, a number of electrocardiographic findings, such as total ST segment deviation, LBBB, left ventricular hypertrophy (LVH), and QT interval prolongation, indicate an increased cardiovascular hazard. Other 12-lead ECG determinations include cardiac rhythm, evolution of the ACS event, response to therapy, and clinical information suggesting an alternative diagnosis. Rhythm determination is quite important, particularly if a compromising dysrhythmia is present. Finally, an alternative diagnosis, such as pulmonary embolism (PE) or acute myopericarditis, can be suggested by the ECG.

In ACS, morphologic changes may occur in the T wave, ST segment, and QRS complex; the PR segment (eg, ST segment depression in atrial infarction or infarct-related pericarditis) can also demonstrate abnormalities, yet the current clinical use of this information is uncertain. The ECG may be normal or nonspecifically abnormal in the presence of an early ACS event, including AMI. The diagnostic abilities of the ECG is further limited by individual variations in coronary anatomy and preexisting coronary disease (eg, previous MI, LBBB, collateral circulation, coronary bypass surgery) and because it does not view the posterior, lateral, and apical left ventricular walls well. Importantly, a single ECG, by itself, is neither 100% sensitive nor 100% specific for AMI and reflects a single point in time of cardiac electrical imaging.

Overreliance on a normal or nonspecifically abnormal ECG in a sensation-free patient with a concerning presentation of anginal chest pain should be avoided. Patients with an initial nondiagnostic ECG who later develop AMI during that hospitalization are often sensation-free or minimally uncomfortable on presentation. Furthermore, the total elapsed time from chest pain onset in patients with normal ECGs does not assist in ruling out the possibility of AMI in patients with chest pain with a single ECG. Although the negative predictive value is high, it is not 100%, even up to 12 hours after the onset of the patient’s chest symptoms. The patient’s history of the event, and the emergency clinician’s interpretation of the history, is the most important diagnostic study and is considered within the context of the interpretation of the ECG.

**Electrocardiographic Abnormalities in Acute Coronary Syndromes.** The earliest electrocardiographic finding in STEMI is the hyperacute T wave (Fig. 68.1), a tall and peaked structure that can appear within minutes of the interruption of blood flow and initiation of acute infarction. It is usually broad-based and asymmetric in structure; the ST segment can be elevated at the J (or junction between the QRS complex and ST segment) point. The hyperacute T wave progresses to ST segment elevation in typical STEMI. This hyperacuity may not be appreciated on the
ST segment elevation is concave and is more prominent as the corresponding S wave (or negative deflection of the QRS complex) becomes deeper. Because of the common occurrence of this finding, it is not a normal variant but rather a normal finding. A helpful point in differentiating normal ST segment elevation from the pathologic ST segment elevation of STEMI is that the latter is a dynamic phenomenon; ECGs recorded sequentially over time, with waxing and waning symptoms, should demonstrate some fluctuation in the degree of ST segment deviation in the presence of ACS.

ST segment depression generally represents subendocardial ischemia. Ischemic ST segment depression is typically horizontal or downsloping; an upsloping contour may be seen but is less frequently associated with ischemia. Subendocardial ischemic ST segment depression may be diffuse, spanning anterior and inferior leads. This finding can be seen in unstable angina or NSTEMI; the distinction is made considering the clinical presentation as well as the results of serial serum markers. The differential diagnosis of ST segment depression includes myocardial ischemia or infarction, repolarization abnormality of left ventricular hypertrophy (the so-called strain pattern), bundle branch block, ventricular paced rhythm (VPR), digoxin effect, hyperkalemia, hypokalemia, PE, intracranial hemorrhage, myocarditis, rate-related ST segment depression, postcardioversion of tachydysrhythmias, and pneumothorax (Fig. 68.3).

ST segment depression in ACS (1) may be seen in NSTEMI, (2) may precede ST segment elevation in STEMI, (3) may reflect initial ECG in that the finding occurs early in the course of acute infarction and is transient with rapid progression to obvious ST segment elevation. The differential diagnosis of the tall T wave includes hyperacute T waves of STEMI, hyperkalemia, benign early repolarization (BER), LVH, LBBB, and acute pericarditis.

As the STEMI progresses, ST segment elevation may become evident, allowing for the diagnosis. Morphologic variations of ST segment elevation (Fig. 68.2) can be seen from the J point at the end of the QRS complex to the apex of the T wave. This upsloping portion of the ST segment usually progresses as it elevates from flat to convex, domed or tombstoned; if flat, it is characterized by horizontal or oblique. At times, the ST segment may be concave or scooped in its elevation with STEMI. This morphology may progress to a convex shape or may stay the same throughout the infarction. The concave morphology, if noted in all elevated ST segments, is atypical for STEMI and is more commonly seen with other ST segment elevation syndromes. ST segment elevation is measured in millimeters; one block on the electrocardiographic tracing is equivalent to 1 mm in height. The baseline is usually considered to be the TP segment, although some advocate use of the terminal point of the PR segment. In general, the most definable, constant baseline evident on the ECG should be used.

ST segment elevation, benign and pathologic, is a common finding on the ECG in adults with chest pain (Table 68.3). Most normal ECGs, especially those of men, may have some degree of ST segment elevation—indeed, upward of 90%. This elevation is seen in the precordial leads and is usually 1 mm or more in men and 1 mm or less in women. The ST segment elevation is concave and is more prominent as the corresponding S wave (or negative deflection of the QRS complex) becomes deeper. Because of the common occurrence of this finding, it is not a normal variant but rather a normal finding. A helpful point in differentiating normal ST segment elevation from the pathologic ST segment elevation of STEMI is that the latter is a dynamic phenomenon; ECGs recorded sequentially over time, with waxing and waning symptoms, should demonstrate some fluctuation in the degree of ST segment deviation in the presence of ACS.

ST segment depression generally represents subendocardial ischemia. Ischemic ST segment depression is typically horizontal or downsloping; an upsloping contour may be seen but is less frequently associated with ischemia. Subendocardial ischemic ST segment depression may be diffuse, spanning anterior and inferior leads. This finding can be seen in unstable angina or NSTEMI; the distinction is made considering the clinical presentation as well as the results of serial serum markers. The differential diagnosis of ST segment depression includes myocardial ischemia or infarction, repolarization abnormality of left ventricular hypertrophy (the so-called strain pattern), bundle branch block, ventricular paced rhythm (VPR), digoxin effect, hyperkalemia, hypokalemia, PE, intracranial hemorrhage, myocarditis, rate-related ST segment depression, postcardioversion of tachydysrhythmias, and pneumothorax (Fig. 68.3).

ST segment depression in ACS (1) may be seen in NSTEMI, (2) may precede ST segment elevation in STEMI, (3) may reflect
CHAPTER 68 Acute Coronary Syndrome

a mirror image of ST segment elevation from posterior MI when
found in the right-sided precordial leads (ie, ST segment depres-
sion in V1 to V3 in posterior MI), and (4) may represent reciprocal
ST segment depression seen with STEMI. With reciprocal ST
segment depression, such changes are seen in leads on the opposite
side of the heart from simultaneous ST segment elevation. For
example, the ST segment depression seen in leads V1 to V3 with a
posterior MI is actually a reciprocal finding resulting from the ST
segment elevation that would be recorded in posterior leads V8
and V9. An inferior MI with ST segment elevation more frequently
manifests reciprocal ST segment depression than the anterior
STEMI. The reciprocal ST segment depression in inferior MI is
best seen in lead aVL, which is 150 degrees removed from lead III
when the positive poles of these leads in the frontal plane are
considered. Anterior STEMI may feature reciprocal ST segment
depression in at least one of the inferior leads (II, III, or aVF).
Reciprocal changes in the setting of STEMI increase the specificity
and positive predictive value of the ECG in AMI and also identify
a patient with a larger infarction, greater chance of cardiovascular
adverse events, and more frequent death. Fig. 68.3 depicts
the various forms of ST segment depression.

T wave inversions, although frequently nonspecific, are a
possible suggestion of chronic ischemic change or ACS; if ACS,
they can represent unstable angina with myocardial ischemia or
NSTEMI. Normally, the T wave is upright in the left-sided leads
I, II, and V1 to V6 and inverted in the right-sided lead aVR. T wave
vectors are variable in leads III, aVL, and aVF. They are usually
normally inverted in V1 and are occasionally normally inverted in
lead V2. The T wave inversions of ACS are classically narrow and
symmetrically inverted (Fig. 68.4). The preceding ST segment is
typically isoelectric and may be bowed slightly upward or concave.
Associated ST segment depression may occur. T wave inversions
are best evaluated in comparison with the most recent prior ECG,
given the multitude of normal variations.

A notable subgroup of ischemic T wave inversions is associated
with Wellens syndrome, which classically manifests with deep

Fig. 68.2. Analysis of ST segment–T wave morphology in acute myo-
cardial infarction (AMI), benign early repolarization (BER), and acute
pericarditis. An analysis of the ST segment–T wave morphology (from
the beginning at the J point to the end at the apex of the T wave) may be
particularly helpful in distinguishing among the various causes of ST
segment elevation (STE) and identifying the STE case. A, The initial
upsloping portion of the ST segment is usually flat (horizontally or
obliquely) or convex in the patient with STEMI. This morphologic obser-
vation, however, should be used only as a guideline; it is not infallible.
B, Non-AMI causes of STE are seen here with concavity of the ST
segment–T wave (left, BER; middle, pericarditis; right, BER). C, Patients
with STE related to STEMI may demonstrate concavity of this portion of
the waveform.

Fig. 68.3. ST segment depression (STD) in acute coronary syndrome. A, Horizontal STD unstable angina
C, Downsloping STD (USAP). D, Upsloping STD (USAP). E, Horizontal STD as seen in lead III in a patient
with anterior wall acute myocardial infarction, an example of reciprocal STD, also known as reciprocal
change.
symmetric T wave inversions (type I) or biphasic T wave changes (type II) in the anterior precordial leads. The presence of biphasic T waves is suggestive of ischemic heart disease. Other electrocardiographic features include isoelectric or minimally elevated (<1 mm) ST segments and no precordial Q waves. This finding may manifest in the anginal or pain-free state and may or may not be accompanied by cardiac marker elevations, which is indicative of a lesion of the left anterior descending artery. The natural history of this presentation is anterior wall STEMI.

Although T wave inversion is sought as a harbinger of ACS, it can also occur as an evolutionary change after MI. In MI without culprit artery reperfusion, the T waves may invert as the ST segments return to baseline, although not particularly deeply. In hearts that are reperfused, T wave inversion may follow ST segment elevation in a biphasic or deeply inverted morphology, an appearance much like the T wave changes of Wellens syndrome. The differential diagnosis of T wave inversion is broad and includes ACS, ventricular hypertrophy, bundle branch block, VPR, myocarditis, pericarditis, PE, pneumothorax, Wolff-Parkinson-White syndrome, cerebrovascular accident, hypokalemia, GI disorders, hyperventilation, persistent juvenile T wave pattern, and normal variants.

The emergency clinician must also consider pseudonormalization of the T wave as a potential electrocardiographic indicator of ACS. Pseudonormalization occurs when, during an acute episode of chest discomfort or anginal equivalent, an apparently normal-appearing T wave on the ECG replaces the normally inverted T wave that existed prior to the development of symptoms. The T wave assumes a normal appearance and may indicate ACS at this presentation.

Q waves are generally representative of irreversible myocardial necrosis but are rarely the sole manifestation of AMI. Pathologic Q waves may emerge within the first hour of infarction but most commonly develop 8 to 12 hours into the infarction. It follows that ST segment elevation with concomitant Q waves does not preclude consideration of emergent reperfusion therapy; a consideration of the patient’s history is vital here with respect to the time of onset of continuous chest discomfort. Q waves may persist after MI as enduring markers of previous infarction on the ECG; in some cases, however, Q waves disappear with time, regardless of whether the infarcted territory was reperfused.

**Anatomic Location of Acute Myocardial Infarction.** The regional distribution of an AMI can be derived from noting the pattern of the various morphologic changes that are described (Table 68.4). Anterior infarctions are primarily evidenced by changes in the precordial leads V₁ to V₃. Septal involvement is reflected by changes in V₃ and V₄. Extension to the lateral wall (ie, anterolateral MI) is evident if the pathologic changes extend beyond leads V₁ to V₃ to include leads V₅, V₆, I, and aVL. In anterior STEMI, reciprocal ST segment depression may occur in leads II and III and aVF. The anterior wall is served by the left anterior descending artery. The first diagonal branch of the left anterior descending artery is likely to be involved when the ST segment elevation extends to leads I and aVL. Isolated occlusion of the diagonal branch of the left anterior descending artery displays similar findings, but of smaller amplitude, as those seen with left anterior descending artery occlusion (ST segment elevation in leads V₃ and V₄, and possibly leads V₁ and V₂, or both, along with ST segment depression in lead II and III, aVF, or both).

Anterior or anterolateral STEMI resulting from left main coronary artery occlusion is a high-risk presentation; the ability to identify this high-risk STEMI subtype further enables the emergency clinician to adjust therapy appropriately. In a patient with symptoms of ACS, ST segment elevation in lead aVR should prompt consideration of occlusion of the left main coronary artery. Pooled data have demonstrated that ST segment elevation in lead aVR (>0.5 mV) is approximately 78% sensitive and 83% specific for left main coronary artery disease; alternatively, this finding in lead aVR may represent multivessel disease, acute proximal left anterior descending occlusion or, less commonly, left circumflex or right coronary occlusion. If ST segment elevation occurs in leads aVR and V₁, greater elevation in the former lead favors left main disease, whereas if it is greater in the latter lead, occlusion in the left anterior descending artery is more likely.

STEMI, ST segment elevation myocardial infarction.

Adapted from Aufderheide TP, Brady WJ: Electrocardiography in the patient with myocardial ischemia or infarction. In Gibler WB, Aufderheide TP, editors: Emergency cardiac care, St. Louis, 1994, Mosby.
In addition to Wellens syndrome as a predictor of proximal left anterior descending artery occlusion, the so-called de Winter presentation is ACS syndrome with proximal occlusion of the left anterior descending artery. The electrocardiographic findings associated with this presentation include prominent T waves with J point depression producing ST segment depression seen in the precordial leads, coupled with ST segment elevation in lead aVR (Fig. 68.6). Like Wellens syndrome, this presentation is associated with a high-risk coronary occlusion pattern, proximal left anterior descending artery occlusions; in addition, these patients are usually ill-appearing, with ongoing chest discomfort. Certain authorities consider this presentation a so-called STEMI-equivalent pattern.

Lateral infarctions are frequently seen in concert with anterior infarction (anterolateral), inferior infarctions (inferolateral), or inferior infarctions with posterior extension (inferoposterolateral). This is because the lateral wall of the heart is variably served by the left anterior descending, right coronary, and left circumflex coronary arteries. Thus, lateral involvement is manifested by changes in some or all of the lateral leads I, aVL, V5, and V6.

So-called high lateral infarctions are restricted to leads I and aVL (Fig. 68.7) and are suggestive of occlusion of the left circumflex coronary artery. ST segment elevation in these leads may be accompanied by reciprocal ST segment depression in leads III, aVF, and V1. Based on cardiac magnetic resonance imaging (MRI) localization of some of these lesions, new Q waves appearing in leads I and aVL (but not V5) indicate a mid–anterior wall MI, previously referred to as a high lateral MI.

Inferior infarctions are characterized by morphologic changes in limb leads II, III, and aVF. The inferior wall of the heart and AV node are served by the right coronary artery in about 90% of cases (right dominant); in the remainder, the left circumflex artery serves that function (left dominant). An inferior STEMI is present if two or more contiguous inferior leads (III, aVF, II) are involved; reciprocal ST segment depression is frequently seen in lead aVL, lead I, or both (Fig. 68.8) and perhaps in the anterior precordial leads, V1 less than V2 and V3. ST segment depression in leads V1 to V3 in the presence of an inferior MI can be caused by reciprocal change, posterior extension, or simultaneous anterior ischemia during inferior infarction. ST segment elevation inferiorly that is greater in lead III than in lead II, accompanied by reciprocal ST segment depression in leads III, aVF, and V1. Based on cardiac magnetic resonance imaging (MRI) accompanied by reciprocal ST segment depression; (2) an upright T wave; (3) tall, wide R wave; (4) R wave amplitude-to-S wave amplitude ratio greater than 2:1; and (5) elevation of the J point.

In addition to Wellens syndrome as a predictor of proximal left anterior descending coronary artery obstruction. In the anterior leads, ST segment depression with depression of the J point is noted along with prominent, hyperacute T wave. In addition, segment elevation is also seen in lead aVR.

**Fig. 68.5.** Anterior wall acute ST segment elevation myocardial infarction (STEMI). ST segment elevation is evident in leads V1 to V6. The morphology seems obliquely straight. Emergency cardiac catheterization revealed a 90% stenotic lesion in the left anterior descending artery; the patient did well after placement of a coronary stent but showed serum marker evidence of acute myocardial infarction (AMI).

**Fig. 68.6.** The de Winter electrocardiographic finding, a pattern associated with proximal left anterior descending coronary artery obstruction. In the anterior leads, ST segment depression with depression of the J point is noted along with prominent, hyperacute T wave. In addition, segment elevation is also seen in lead aVR.
1 (Fig. 68.9). The combination of horizontal ST segment depression with an upright T wave increases the diagnostic accuracy of the 12-lead ECG for acute posterior MI. Furthermore, in that the tall R wave in the right precordial leads is actually the mirror image of a posterior Q wave, its emergence may be delayed in posterior infarction. Additional leads (posterior leads V8 and V9) increase the sensitivity for detection of acute posterior MI. Patients with inferior MI who have ST segment depression in leads V1 to V3 or ST segment elevation in the posterior leads V8 and V9 generally have larger infarction zones, lower resultant ejection fractions, and higher rates of cardiovascular morbidity and mortality than patients with isolated inferior MI. Cardiac MRI suggests that these so-called posterior infarctions producing tall R waves in leads V1 and V2 are actually lateral left ventricular wall MIs. A consensus document has suggested reclassifying posterior infarctions as inferobasal infarctions.

Right ventricular infarctions rarely occur in isolation and are usually associated with inferior or inferoposterior MI, although only about one-third of inferior infarctions have associated infarction of the right ventricle. At times, an anterior MI involves some (but <50%) of the right ventricular wall. It follows that occlusion in any of the major coronary arteries may lead to right ventricular infarction, although the right coronary is most commonly involved. Clinically, right ventricular infarction features include elevated jugular venous pressure and hypotension in the

Fig. 68.7. Anterolateral acute myocardial infarction. ST segment elevation is seen in leads I, aVL, V5, and V6. A proximal left anterior descending artery lesion with thrombus was noted at emergent percutaneous coronary intervention.

Fig. 68.8. Inferior acute myocardial infarction with reciprocal changes. Marked ST segment elevation is seen inferiorly (leads II, III, and aVF). Classic reciprocal ST segment depression is evident in leads I and aVL.

Fig. 68.9. Isolated posterior wall acute myocardial infarction (PMI)—complexes from right precordial leads and posterior leads. The right precordial leads V1 and V2 reveal typical findings of PMI with prominent R wave (A), ST segment depression (STD; B), and upright T wave (C). The posterior leads V8 and V9 in the same case demonstrate ST segment elevation (STE) (arrows), confirming isolated PMI.
setting of inferior wall MI. These findings, however, are also suggestive of pericardial tamponade. Nitrate-induced hypotension is also suggestive of right ventricular infarction and of tamponade. Initial therapy for both would include volume loading and avoidance of vasodilators or other agents that may lower the blood pressure.

ST segment elevation in lead V₁ in the setting of inferior STEMI (ie, ST segment elevation in leads II, III, and aVF rather than in the setting of concomitant ST segment elevation in all anterior precordial leads) is suggestive of right ventricular infarction. This is not surprising in that lead V₁ is the most rightward, or right ventricular–oriented, of the precordial leads. These changes occasionally extend into lead V₈ with right ventricular infarction. ST segment elevation is usually greater in lead III than in leads II and aVF when right ventricular infarction coexists with inferior STEMI. This logically follows in that the positive vector of lead III (in the frontal plane) is more rightward than that of leads II and aVF. Application of so-called right-sided precordial leads is the best means to diagnose right ventricular infarction with the ECG. These leads, as a mirror image of the left precordial leads II and aVF, demonstrate ST segment elevation with right ventricular infarction. These leads, as a mirror image of the left precordial leads II and aVF when right ventricular infarction coexists with inferior MI. Caution is required when interpreting ST segment elevation in the setting of inferior MI. Benign early repolarization (BER) may mimic infarction (see Table 68.3). ST segment elevation on the ECG in the setting of inferior MI is not the most common cause of ST segment deviation in adults with chest pain who are suspected of AMI. Benign early repolarization is a normal electrocardiographic variant that does not imply, nor exclude, ACS or CAD. BER includes the following electrocardiographic characteristics: (1) ST segment elevation; (2) upward concavity of the initial portion of the ST segment; (3) notching of the terminal portion of the QRS complex at the J point (ie, junction of the QRS complex with the ST segment); (4) symmetric concordant T waves of large amplitude; (5) diffuse ST segment elevation on the ECG; and (6) relative temporal stability over the short term, although these changes may regress with advancing age. J point elevation is usually less than 3.5 mm, and the concave ST segment is usually elevated less than 2 mm in the precordial leads (although it may be elevated as much as 5 mm in some cases) and 0.5 mm in the limb leads. Maximal ST segment elevation in BER is typically seen in leads V₁ to V₆. Isolated BER is rare and should prompt reconsideration of STEMI. STEMI with concomitant right ventricular infarction have larger infarcts and experience more in-hospital complications and higher mortality rates.

Electrocardiographic Differential Diagnosis of ST Segment Elevation. ST segment elevation on the ECG in the context of a presentation compatible with ACS is considered to represent STEMI until proven otherwise. Several other conditions, particularly LBBB and LVH, also feature ST segment elevation that mimics infarction (see Table 68.3). ST segment elevation resulting from STEMI is not the most common cause of ST segment deviation in adults with chest pain who are suspected of AMI. Caution is required when interpreting ST segment elevation in regard to the decision to initiate reperfusion treatment, whether it be PCI or fibrinolytic therapy.

Benign early repolarization is a normal electrocardiographic variant that does not imply, nor exclude, ACS or CAD. BER includes the following electrocardiographic characteristics: (1) ST segment elevation; (2) upward concavity of the initial portion of
**Fig. 68.12.** Benign early repolarization. Note the upwardly concave ST segment elevation, best seen in leads V4 to V6. The T waves are relatively large in the same leads. Subtle notching is also seen at the J point in leads V4 and V5. Prior electrocardiograms of this patient were unchanged.

**Fig. 68.13.** Pericarditis. This tracing demonstrates several classic signs of pericarditis: (1) sinus tachycardia; (2) diffuse, concave upward ST segment elevation; (3) PR segment depression, best seen in lead II; and (4) PR segment elevation in lead aVR.

height. Occasionally, the initial contour is obliquely flat, but convex or domed ST segment morphology is strongly suggestive of STEMI. The ST segment elevation is usually seen in all leads with the exception of aVR (where it is depressed); V6 is variable. Focal pericardial inflammation manifests as a more accentuated change in the leads reflecting the affected region. PR segment depression is an insensitive yet specific associated electrocardiographic finding in pericarditis, which is typically best seen in the inferior leads and lead V6; correspondingly, PR segment elevation may be evident in lead aVR (Fig. 68.13; see Fig. 68.11B). In that ST segment changes are encountered in these patients, the most appropriate term applied is myopericarditis, rather than pericarditis. Recall that the pericardium is electrically silent; thus, electrocardiographic changes result from epicardial irritation and ST segment elevation—hence, the term myopericarditis.

Left ventricular aneurysm (LVA), wherein a focal area of myocardium paradoxically bulges outward during systole, has characteristic electrocardiographic changes that can be difficult to differentiate from those of STEMI. Considerable overlap exists between populations of patients with potential for STEMI and LVA, and the electrocardiographic changes of LVA tend to be regional rather than diffuse. Anatomically, LVA is usually found anteriorly, and changes are most often seen in leads V1 to V6 and leads I and aVL. ST segment elevation may be of any morphology (e.g., convex or concave), and Q waves may be present (Fig. 68.14). The calculation of the ratio of the amplitude of the T wave to the QRS complex may help distinguish acute anterior MI from LVA. It has been shown that if the ratio of the amplitude of the T wave to the QRS complex exceeds 0.36 in any single lead, the ECG probably reflects STEMI. If the ratio is less than 0.36 in all leads, however, the findings are probably the result of a ventricular aneurysm.

LBBB is a confounding pattern that reduces the ECG’s ability to detect ACS. Furthermore, in a clinical situation strongly suggestive of ACS, a new LBBB is consistent with AMI in a number of case. Its sole presence, however, should not prompt AMI management. LBBB, whether new or preexisting, shares many similarities to various electrocardiographic findings of ACS. In the right precordial leads (leads V1 to V3), ST segment elevation and tall, vaulted, upright T waves mimic those seen in anterior STEMI. The QS pattern of LBBB in these leads resembles the Q waves seen in infarction. Depressed ST segments with T wave inversions are seen
CHAPTER 68 Acute Coronary Syndrome

the other two criteria, further testing is recommended before one can conclude that the ECG is indicative of AMI. Subsequent literature reports have yielded mixed reviews of the Sgarbossa criteria for the diagnosis of AMI in the presence of LBBB. Ultimately, the approach to the patient with LBBB and possible AMI remains complicated. If the clinical presentation is consistent with AMI, diagnostic adjuncts to the history and physical examination (eg, serial ECGs, comparison with prior ECGs, echocardiography, serum cardiac marker measurement) should be liberally used when the ECG is not diagnostic for acute infarction as noted by the Sgarbossa criteria. A newly noted LBBB, occurring in patient with a very convincing clinical impression of AMI, should be considered a high-risk presentation; AMI in this situation is likely.

VPRs can mimic and mask the manifestations of AMI. VPRs originating in the right ventricular apex create a wide QRS complex, with a pseudo-LBBB pattern. As with LBBB, the right precordial leads in VPR typically feature predominantly negative QRS complexes with discordant ST segments and T waves that are elevated and tall or vaulted, respectively. Unlike LBBB, however, VPR originating in the right ventricular apex often yields a predominantly negative QRS complex in leads V3 and V6 as well; this

in some or all of the lateral leads (leads V2, V3, I, and aVL) in LBBB; both of these resemble ischemic changes seen in ACS. However, these findings in LBBB are merely expressions of the so-called rule of appropriate discordance. The ST segment and T wave vectors are expectedly discordant, or opposite in direction, to the major vector of the QRS complex in those leads. Because LBBB is a frequent finding on the ECG of a patient at risk for CAD, the normal findings in LBBB (Fig. 68.15) and presentation of AMI in a patient with LBBB must be distinguished.

Sgarbossa and colleagues used a large AMI database to obtain a population of patients with LBBB and serum marker confirmation of AMI. Three independent electrocardiographic predictors of AMI in the presence of LBBB were identified: (1) ST segment elevation of at least 1 mm that is concordant with the QRS complex (Fig. 68.16); (2) ST segment depression of at least 1 mm in lead V1, V2, or V3 (see Fig. 68.16A); and (3) ST segment elevation of at least 5 mm that is discordant with the QRS complex (see Fig. 68.16B). These findings were assigned weighted scores of 5, 3, and 2, respectively. For accuracy in diagnosis, a specificity of 90% requires a score of at least 3. Thus, if an ECG features only discordant ST segment elevation of 5 mm or more but neither of the other two criteria, further testing is recommended before one can conclude that the ECG is indicative of AMI. Subsequent literature reports have yielded mixed reviews of the Sgarbossa criteria for the diagnosis of AMI in the presence of LBBB. Ultimately, the approach to the patient with LBBB and possible AMI remains complicated. If the clinical presentation is consistent with AMI, diagnostic adjuncts to the history and physical examination (eg, serial ECGs, comparison with prior ECGs, echocardiography, serum cardiac marker measurement) should be liberally used when the ECG is not diagnostic for acute infarction as noted by the Sgarbossa criteria. A newly noted LBBB, occurring in patient with a very convincing clinical impression of AMI, should be considered a high-risk presentation; AMI in this situation is likely.

VPRs can mimic and mask the manifestations of AMI. VPRs originating in the right ventricular apex create a wide QRS complex, with a pseudo-LBBB pattern. As with LBBB, the right precordial leads in VPR typically feature predominantly negative QRS complexes with discordant ST segments and T waves that are elevated and tall or vaulted, respectively. Unlike LBBB, however, VPR originating in the right ventricular apex often yields a predominantly negative QRS complex in leads V3 and V6 as well; this

![Fig. 68.14. Left ventricular aneurysm. This is a representative example of a 12-lead electrocardiogram from a patient with an anterior left ventricular aneurysm. Note the well-developed, completed Q waves in leads V2 through V6 and absence of reciprocal changes in contralateral leads. (Adapted from Aufderheide TP, Brady WJ: Electrocardiography in the patient with myocardial ischemia or infarction. In Gibler WB, Aufderheide TP, editors: Emergency cardiac care, St. Louis, 1994, Mosby, pp 196–216.)](image1)

![Fig. 68.15. Left bundle branch block (LBBB; normal). This tracing demonstrates the classic findings of LBBB: (1) QRS complex width > 0.12 sec; (2) absence of Q wave in lead V6; (3) broad monophasic R wave in leads V5, V6, I, and aVL; (4) discordant ST segment–T wave changes in leads V1 to V3 (simulating acute myocardial infarction), I, and aVL. A first-degree atrioventricular block is also apparent.](image2)
ACS. Sgarbossa and associates have advanced criteria for the detection of AMI in the presence of VPR that were derived from the same database of patients and are essentially the same as the LBBB criteria: (1) ST segment elevation of at least 5 mm discordant with the QRS complex; (2) ST segment elevation of at least 1 mm concordant with the QRS complex; and (3) ST segment depression of at least 1 mm in lead V1, V2, or V3 (Fig. 68.17).

LVH may mimic or obscure ACS on the ECG. LVH may feature prominent left-sided forces, manifesting as large rS or QS is oriented leftward and slightly downward, whereas the impulse generated from the pacemaker wire is oriented superiorly. Furthermore, small vertical pacemaker spikes immediately preceding the QRS complex should be a clue to VPR although, at times, these deflections are hard to detect on the 12-lead ECG.

Limited data exist to guide the emergency clinician in interpreting the 12-lead ECG in this setting. As with the LBBB scenario, the VPR pattern represents a significant confounding variable in the evaluation of the patient with chest pain suspected of having Fig. 68.16. Acute myocardial infarction (AMI) in left bundle branch block (LBBB). A, Using the Sgarbossa criteria, there is strong evidence of AMI because of the concordant ST segment elevation greater than 1 mm in leads II, V5, and V6. Also suggestive is the ST segment depression seen in V2. B, Again, applying the Sgarbossa criteria to this tracing with underlying LBB. B, AMI is strongly suggested. There is concordant ST segment elevation in leads V5 and V6 that appears to exceed 1 mm; furthermore, there is excessively discordant ST segment elevation in leads V1 and V4, probably greater than 5 mm.
complexes in the right precordial leads, yet these changes seldom extend beyond V1 and V2 in the case of LVH. Consistent with the rule of appropriate discordance, the leads demonstrating such a pattern feature discordant ST segment elevation and tall vaulted T waves, paralleling the changes of AMI. The initial portion of the elevated ST segment in LVH is generally concave, as opposed to the obliquely straight or convex pattern that usually (but not always) is seen with ST segment elevation in AMI. In LVH, the left precordial leads (and, at times, leads I and aVL) may show evidence of a repolarization abnormality (or strain pattern), with ST segment depression and asymmetrically inverted T waves. The presence of this strain pattern in the left precordial leads is reassuring when ST segment elevation and tall T waves in the right precordial leads are being attributed to LVH rather than to AMI because one is essentially the mirror image of the other. The changes in LVH should be static over time (Fig. 68.18).

Takotsubo cardiomyopathy is referred to as left apical ballooning or so-called broken heart syndrome. It features ST segment elevation (or deep T wave inversions) without evidence of obstructive CAD. Positive serum markers for cardiac ischemia may be present, as well as hemodynamic compromise. It occurs principally in postmenopausal women and characteristically is triggered by intense emotional stress. Ballooning of the left ventricular apex is seen on ventriculography or echocardiography. Prognosis is excellent, typically with recovery of normal wall motion within 1 month or less.

Fig. 68.17. Permanent right ventricular paced pattern with acute myocardial infarction (AMI)—ventricular paced rhythm. A, Appropriate ST segment–T wave findings in the patient with a paced rhythm. B, Serial electrocardiogram from the patient in A, revealing evolution of changes worrisome for ST segment elevation myocardial infarction (STEMI), including concordant ST segment elevation in leads I and aVL consistent with lateral wall STEMI.
Non–ST Segment Elevation Myocardial Infarction. Non–ST segment elevation myocardial infarction, or NSTEMI, supplants non–Q wave MI, previously termed subendocardial infarction. Precise terminology is difficult because Q waves may disappear with time and the criteria for significant Q waves vary. Moreover, transient ST segment elevation may simply be missed on the ECG. Nonetheless, it is useful to describe the entity wherein there is serum marker evidence of MI in the appropriate clinical scenario but no documented ST segment elevation.

Pathophysiologically, total occlusion of the diseased artery may not have occurred, or the infarct zone may have been partially spared by collateral circulation or therapeutic intervention. Electrocardiographic manifestations of NSTEMI include ST segment depression and T wave inversion, which may be deep and symmetric; nonspecific ST segment and/or T wave abnormalities may also be seen in the NSTEMI presentation. Absence of STEMI, however, does not necessarily translate to better outcomes. Previous studies have demonstrated that patients with ST segment depression on the initial ECG have an in-hospital mortality rate similar to that of patients with ST segment elevation or LBBB (15%–16%). Furthermore, ST segment depression in leads V₃ to V₆ may herald true posterior infarction on the 12-lead ECG. Acute posterior (inferobasal) MI is one entity wherein emergent fibrinolysis or PCI is potentially indicated in the absence of ST segment elevation on the 12-lead ECG.

Electrocardiographic Adjuncts in the Diagnosis of Acute Coronary Syndrome. Additional lead ECGs can increase sensitivity for AMI by evaluating regions of the heart prone to electrical silence on the 12-lead tracing. Usually, additional lead ECGs use posterior leads (V₆ and V₇) and right ventricular (V₉) electrodes, thus constituting the 15-lead ECG (Fig. 68.19). Posterior leads V₆ and V₇ are placed under the tip of the left scapula and at the left paraspinal area at the same level as leads V₃ to V₄. Morphologic changes in the posterior leads may be subtle, mainly because of the increased distance between these electrodes and posterior wall of the heart.

Electrocardiographic imaging of the right ventricle is enhanced with the use of the right-sided chest leads V₁R to V₆R (also termed RV₁ to RV₆). These leads are placed in mirror image fashion across the right precordium. Of the right precordial leads, V₉R has the highest sensitivity for right ventricular infarction and is the lead of choice to include in the 15-lead tracing. Morphologically, less pronounced changes can be expected in the right-sided chest leads because of the relatively thinner wall of the right ventricle.

Use of the 15-lead ECG may improve diagnostic precision but does not appear to affect the rate of AMI diagnosis, use of reperfusion therapy, disposition, or outcome in all ED patients with chest pain evaluated for ACS. It has been shown that in the subset of ED ACS patients identified as candidates for admission to the cardiac care unit (ie, high-risk patients), the 15-lead ECG increased the sensitivity of ACS detection by 12%. Possible applications for additional lead ECGs include the following: (1) ST segment changes (depression or elevation) in leads V₁ to V₆, in an isolated lead or in more than one; (2) equivocal ST segment elevation in the inferior (II, III, aVF) or lateral (I, aVL) limb leads, or both; (3) all inferior STEMI; and (4) hypotension in the setting of ACS. Additional lead applications can be used, including the 18- and 24-lead ECG; electrocardiographic body mapping with use of multiple electrocardiographic leads, such as the 80-lead ECG, can also be used. In general, the emergency clinician can image larger segments of the heart with more electrocardiographic leads in use. It is suggested that these additional lead ECGs, including body mapping, can increase the rate of STEMI diagnosis and thus the number of patients who are candidates for emergent reperfusion therapy.

Body surface mapping increases the amount of electrocardiographic data for processing and decision-making. Whereas serial ECGs and ST segment trend monitoring increase the period of time over which data are collected on a 12-lead ECG, body surface mapping increases the number of electrodes used to gather data and increases the vantage points from which the heart is evaluated. Various devices use 40 to 120 leads. With an 80-electrode device, 64 chest and 16 back electrodes are applied in a vestlike fashion with self-adhering strips. Recording from all electrodes simultaneously, the body surface map enters ST segment elevation and depression data into a computer, which transforms the data into a color-coded torso image. With red representing ST segment elevation, blue signifying ST segment depression, and green reflecting normal, the degree of disease is also expressed in terms...
 Fifteen-lead ECG (ECG) and that inferior, seen the lateral, V posterior, less than right ventricular degree that electrocardiogram Note leads of V pronounced and in AMI are approximately 60% and 90%, respectively. Serial ECGs and symptoms consistent with ACS, 12 hours of continuous monitoring in a coronary care unit demonstrated that in patients admitted with nondiagnostic initial ECGs and symptoms consistent with ACS, 12 hours of continuous 12-lead electrocardiographic monitoring in a coronary care unit revealed that only serum cardiac marker elevation and eventually normal ECG only STEMI had adverse outcomes similar to those encountered in the 12-lead STEMI patients, yet these individuals were treated much less aggressively.

Serial ECGs and ST segment trend monitoring overcome the limitations of the single snapshot of a 12-lead ECG. The use of increased electrocardiographic surveillance demonstrates diagnostic benefit in patients with recurrent or continuous chest pain, particularly patients with an initially normal nondiagnostic or possible ST segment mimicking syndrome ECG (eg, ST segment elevation potentially resulting from BER) in whom there is a high clinical suspicion for ACS. We know that the examination of ST segment trends (measured every 20 seconds for at least the first hour) and automated serial ECGs (at least every 20 minutes) in ED patients with chest pain can significantly increase the sensitivity and specificity for detection of STEMI (16%) and ACS compared with just the initial ECG (Fig. 68.20). Previous studies have demonstrated that in patients admitted with nondiagnostic initial ECGs and symptoms consistent with ACS, 12 hours of continuous 12-lead electrocardiographic monitoring in a coronary care unit setting revealed that only serum cardiac marker elevation and presence of ST segment episodes (defined as ST segment elevation or depression > 1 mm different from baseline that endured for at least 1 minute) predict cardiac death or MI.

Limitations of Electrocardiography in Acute Coronary Syndrome. The sensitivity and specificity of a single ECG for AMI are approximately 60% and 90%, respectively. Serial ECGs in the setting of continued or recurrent pain in a patient with a higher clinical suspicion for ACS and an initially nondiagnostic ECG increase the diagnostic value. The initial ECG is nondiagnostic in approximately 50% of patients in the ED who are ultimately diagnosed with STEMI. Moreover, nondiagnostic and even normal ECGs do not exclude the diagnosis for AMI in that about 20% of patients ultimately diagnosed with AMI have nondiagnostic ECGs earlier in their course. At time elapses from symptom onset to electrocardiographic recording, the ability of the ECG to exclude AMI does not markedly increase. Thus, in a patient with higher clinical suspicion for ACS, a single normal or nondiagnostic ECG does not ensure the absence of ACS, even if the ECG was recorded well after the onset of symptoms. In patients being evaluated for ACS, only serial electrocardiography, combined with serial cardiac marker determinations, can exclude AMI and, even then, UA without actual myocardial necrosis may be present.

Chest Radiography

The chest radiograph provides information concerning the application of therapies (eg, an evaluation of mediastinal width in the consideration of fibrinolytic agent use and determination of pulmonary congestion in the consideration of acute parenteral β-adrenergic blocking therapy). Furthermore, the presence of CHF on the chest radiograph increases risk in AMI patients who may benefit from an aggressive therapeutic approach.

There is radiographic evidence of pulmonary congestion in approximately one-third of AMI patients. AMI patients who develop CHF have increased mortality, as reported by the Killip classification. The chronicity of the CHF syndrome may also be suggested by heart size. Patients with AMI complicated by pulmonary edema who have a normal heart size usually have no past
Biochemical markers play a pivotal role in the diagnosis, risk stratification, and guidance of treatment of ACS. The European Society of Cardiology and ACC have defined the criteria for AMI history of CHF. AMI is the most frequent cause of pulmonary edema with a normal cardiac size. In other cases, patients with AMI and cardiomegaly, with or without pulmonary edema, frequently have a preexisting history of CHF, anterior wall infarct, and multiple-vessel CAD (Fig. 68.21).

**Fig. 68.20.** Serial electrocardiography. A, Representative example of lead III in a patient with chest pain and an initially nondiagnostic electrocardiogram depicting the evolution of ST segment elevation myocardial infarction (STEMI). B, Representative example of lead V2 in a patient with the left ventricular hypertrophy pattern. Serial sampling of this patient with ongoing chest pain and a confounding electrocardiographic pattern reveals the progression to STEMI. C, Representative example of lead V3 in a patient with left bundle branch block and evolving acute myocardial infarction (AMI). D, Representative examples of lead III in a patient with chest pain and noninfarctional ST segment elevation (STE). Note the lack of change (degree of elevation as well as morphology of elevation) over time in this patient with benign early repolarization.

**Fig. 68.21.** Chest radiographs in patients with acute coronary syndrome. A, Cardiomegaly. B, Borderline cardiomegaly with pulmonary edema.

**Serum Markers**

Biochemical markers play a pivotal role in the diagnosis, risk stratification, and guidance of treatment of ACS. The European Society of Cardiology and ACC have defined the criteria for AMI.
diagnosis on biochemical grounds because specific markers, particularly troponins, indicate irreversible cell damage. In the past, detection of AMI by characteristic enzyme level elevations over days within the hospital was sufficient to establish the diagnosis of AMI because there was no specific therapy to reverse or prevent the developing myocardial necrosis. The advancement in diagnostic tests, as well as medical and interventional therapies for AMI, has made the diagnosis and intervention of AMI in the first minutes to hours of the ED visit not only possible, but essential.

For patients with a nondiagnostic ECG, early elevation of serum markers specific for myocardial necrosis (troponin I or T) confirms a presumptive diagnosis of NSTEMI. Caution is advised, however, when a single initial serum marker level is not elevated. This single test, in the first hours following symptom onset, is too insensitive to be used to support a decision that the patient can be discharged or determine that no acute coronary event has occurred. The patient’s history remains the most vital portion of the diagnostic evaluation of potential ACS. Serial testing substantially improves the sensitivity of these tests for AMI (Table 68.5 and Fig. 68.22), but if the patient’s presentation is consistent with unstable angina, no marker can be used to rule out that diagnosis. A sensitive and specific marker to identify myocardial ischemia without myocardial necrosis is not yet available.
Troponins. Because of their superior sensitivity and specificity compared with other biochemical markers, cardiac troponins are the best markers for the identification of myocardial cell injury. Because of this, cardiac troponin (cTn) is the only cardiac marker referenced in the universal definition of MI and is used in isolation in the most recent validated standardized decision rules for the evaluation of ACS. Two myocardium-specific proteins, myocardial troponin I (TnI) and troponin T (TnT), precede the release of creatine kinase (CK-MB) into the serum. The cardiac troponins are genetically distinct from troponin forms found in other muscle tissue. TnI and TnT are very similar in their diagnostic and prognostic value and their serum kinetics and rates of increase and decrease associated with myocardial ischemia, infarction, and ACS.

The biokinetics of troponin release relate to the location of the protein within the cell. Normally, small quantities of troponins are free in the cytosol, and most is entwined in the muscle fiber. After injury, a biphasic rise in serum troponin levels corresponds to early release of the free cytoplasmic proteins, followed by a slower and greatly prolonged rise, with breakdown of the actual muscle fiber. The slow destruction of the myocardial cell contractile proteins provides a sustained release of the troponins for 5 to 7 days. Serum troponin levels begin to rise measurably in the serum at about the same time as CK-MB level elevations become detectable, as early as 2 to 3 hours after onset, but troponin levels remain elevated for 7 days or more.

The cardiac-specific troponins, determined serially, are highly sensitive for the early detection of myocardial injury. A positive test result is associated with significant risk, and serial negative results predict low risk. A single troponin measurement on presentation, however, has limited value in excluding AMI in the first hours of symptom onset and no ability to detect UA without infarction because cell injury is required. Serial measurements, particularly when performed at least 6 hours after symptom onset (as early as 2–3 hours when using newer, high-sensitivity assays), markedely improve the sensitivity of the cardiac troponins for AMI, and the pattern of rise may assist in determining the acuity of the event. These serial measurements of troponin levels are to assess for a change in serum concentration over time (delta). Responding to the absolute change in serum concentration, rather than the relative change, has been shown to be more accurate in the diagnosis of AMI. The highly sensitive troponin assays produce positive results after AMI reliably within several hours. These newer assays, however, seem to yield more false-positive results and are still limited in sensitivity because they do not detect UA. As with most tests, the new generation of highly sensitive troponin assays become more sensitive, they lose specificity for ACS evaluation and diagnosis. Recent evidence has indicated that we may have reached a point of maximum diagnostic return with regard to troponin assay sensitivity, in which increased sensitivity may only complicate the evaluation for ACS.

Because cardiac troponins are not found in the serum of healthy individuals, an abnormally elevated level is defined as that exceeding the 99th percentile in a healthy population. Sensitivity to detect abnormal low troponin levels, however, varies among the multiplicity of existing assays, particularly with respect to TnI. Emergency clinicians, therefore, must be familiar with the sensitivity and limitations of the particular assay used at their institution and cutoff concentrations for clinical decisions.

Data indicate that even very low values of troponin level elevations are associated with a significantly adverse clinical prognosis. This is true not only in patients with chest pain, but also in asymptomatic individuals in the general population for whom data have shown that detectable serum troponin levels, using a high-sensitivity troponin assay, are associated with the presence of structural heart disease and all-cause mortality.

In a number of studies, up to 33% of patients diagnosed with UA with normal CK-MB levels had elevated troponin levels, indicating the marker’s improved sensitivity for myocardial cell injury. The risk of these patients for cardiac events and mortality is similar to that of patients diagnosed with AMI by traditional World Health Organization (WHO) criteria and has led to the redefinition of AMI on the basis of biochemical markers. It has been shown that there is almost a linear correlation between increasing troponin levels and risk of cardiac events and mortality, even in patients with a nondiagnostic ECG and normal CK-MB levels. Small elevations of troponin levels may be used as an objective measure of preinfarcts that characterize UA and are associated with increased risk of infarction in the near term. Marked elevations in troponin levels consistent with AMI represent further progression along the continuum of ACS toward so-called traditional AMI. Cardiac troponin levels may also guide ACS treatment. Data from earlier studies have suggested that patients with elevated troponin levels who are treated with an early invasive interventional strategy within 48 hours have a marked improvement in recurrent ischemia, infarction, and mortality in the short term and at 6 months. These studies included patients without major electrocardiographic criteria for immediate interventional reperfusion strategies.

It is likely that the improved sensitivity of troponin as a marker has captured a high-risk ACS population not previously diagnosed or treated. It is important to note that elevated troponin levels identify patients with UA or NSTEMI who stand to gain the greatest benefit from an early invasive strategy with coronary angiography and revascularization.

Elevated troponin levels occur in a variety of cardiac and noncardiac conditions unrelated to the typical ACS pathophysiology. Cardiac conditions that can result in significant increased troponin levels in patients without evidence of ACS include myocarditis, pericarditis, CHF, LVH, and nonpenetrating cardiac trauma. Although the presence of elevated troponin levels in these conditions might be considered false-positive results, studies have supported the contention that the source of these levels is underlying noninfarction myocyte injury that occurs with these conditions. Moreover, elevated troponin levels in many of these non-ACS cardiac conditions have prognostic significance.

Troponin level elevations can also be seen in noncardiac conditions, including PE, sepsis, extreme physical exertion, renal insufficiency, and even essential hypertension. Troponin level elevation may result from right ventricular dysfunction and myocyte injury in the case of submassive and massive PE and is a significant predictor of an adverse outcome. Similar elevated troponin levels have been reported in patients with sepsis and critically ill patients with multiple organ system failure. In each of these subsets of patients, troponin level elevations are associated with increased morbidity and mortality.

Elevated troponin levels are commonly seen in asymptomatic patients with end-stage renal disease. Earlier studies in asymptomatic hemodialysis patients using a high-sensitivity troponin assay have shown that as many as 100% of the serum samples taken will have measurable troponin levels exceeding the 99th percentile value. This finding may relate to the high prevalence of cardiac disease in this population rather than any reduced renal clearance and may still represent evidence of subclinical myocardial damage. The TnT isoform is associated with elevated levels in renal failure more often than TnI, particularly in patients undergoing hemodialysis. Elevated troponin levels in the setting of renal failure are associated with increased risk of death and major cardiac and vascular morbidity and should not be ascribed to chronic renal failure unless old records are available to corroborate that the elevated troponin level is actually the patient’s normal baseline level.
Other Serum Markers. Creatinine phosphokinase (CK) is found in large quantities, not only in cardiac muscle but also in skeletal muscle, brain, kidney, lung, and GI tract. Myocardial cells are the most abundant potential sources of CK-MB; thus, the appearance of CK-MB in the serum is highly suggestive of MI. The CK-MB fraction remains the best alternative to troponin levels as a cardiac marker. In the setting of AMI, CK-MB is released and is detectable in the serum as early as 3 hours after onset of the necrosis, peaks at 20 to 24 hours, and becomes normal within 2 to 3 days after injury. Unfortunately, skeletal muscle does contain small amounts of CK-MB, particularly the pelvic musculature. Abnormal CK-MB level elevations may be seen in patients with trauma, muscular dystrophies, myositis, and rhabdomyolysis and after extremely vigorous exercise. Because of this lack of specificity, CK and CK-MB have been seen a gradual decrease in clinical use in recent years. As troponin level assays have become more sensitive, with detectable levels in the serum even preceding CK and CK-MB changes, CK-MB has been virtually eliminated from the modern clinical decision rules targeting ACS evaluation in the ED. The diagnostic value of CK-MB is improved by requiring that the serum level not only be elevated but also be at least 5% of the total CK level (the CK-MB fraction or ratio). False-positive elevations can occur with noncoronary conditions, such as pericarditis, myocarditis, skeletal muscle disease, rhabdomyolysis, trauma, and exercise. In presentations in which dual biomarkers are obtained, myoglobin, however, is not currently distinguishable immunologically from skeletal muscle myoglobin. Thus, the myoglobin level is elevated in any clinical situation involving the skeletal muscle, such as trauma, exercise, and significant systemic illness. In addition, myoglobin level increases are seen in patients with renal failure because of reduced clearance. Despite its high sensitivity for AMI, particularly early in the course of ACS, myoglobin has largely fallen out of favor due to its extreme lack of specificity for ACS or myocardial injury in general.

Troponin, CK, and myoglobin levels are all measures of myocardial necrosis. Biochemical assays for potential new cardiac markers for necrosis are being developed in the hope of finding those with improved sensitivity, risk determination capability, and prognostic power. One such new cardiac-specific myonecrosis marker is heart-type, fatty acid–binding protein. Other potential markers with usefulness in ACS include those that may detect ischemia before actual necrosis and plaque instability or inflammation.

Episodes of ischemia and inflammation can result in biochemical changes before actual irreversible cell necrosis. Ischemia-modified albumin (so-called cardiac albumin) is a potentially useful ACS biomarker that reportedly detects early myocardial ischemia rather than the later myocyte necrosis and its level may be elevated even earlier than myoglobin. Other potential ischemia markers include unbound free fatty acid and whole blood choline levels. A variety of biochemical markers for inflammation and plaque instability may have value in evaluating the risk of a cardiac event. Chief among these are the inflammatory markers C-reactive protein (CRP) and high-sensitivity CRP (hsCRP), which have long-term prognostic value for cardiac events in healthy individuals and potential short-term prognostic value when combined with other markers for ACS. Other inflammatory markers include interleukin-6 and tumor necrosis factor alpha. Elevated plasma levels of myeloperoxidase, an abundant leukocyte enzyme found in vulnerable coronary plaques that have ruptured, predict the short-term risk of adverse cardiac events, even with negative cardiac troponin levels and no evidence of myocardial necrosis. None of the biochemical markers of ischemia (without necrosis) or inflammation have yet shown significant diagnostic value for ACS in the ED setting.

Markers of hemodynamic status, including the natriuretic peptides, may also be useful in the evaluation of ACS patients. These markers have shown value in determining future prognosis, rather than in making the diagnosis of ACS in the ED. These markers, such as B-type natriuretic peptide (BNP) and NT-proBNP (N-terminal pro-BNP), are released from cardiac myocytes in response to increases in ventricular wall stress. BNP is generally used as a marker for CHF but is a useful adjunct to the standard cardiac markers and has good predictive power for recurrent ACS events and cardiac-related deaths, as well as CHF exacerbations, in patients with AMI. Moreover, the natriuretic peptides are excellent predictors of short- and long-term mortality in patients with UA, NSTEMI, and STEMI.

Multiple Marker Strategies. Traditionally, multimarker approaches to ACS evaluation have been standard practice in the ED. However, with the advent of highly sensitive troponin assays, multiple studies have shown limited benefit to additional markers in the ED evaluation of ACS. In addition to simplifying the evaluation, it has been shown that there is significant potential cost savings to the hospital by limiting excess cardiac biomarker testing. The multimarker approach does not appear to offer benefit over individual troponin level evaluations for ACS and is therefore no longer recommended.

Exercise Testing

Exercise stress testing for ED patients is feasible. Previous studies in ED patients with low-risk chest pain (5% incidence of CAD), who underwent exercise testing after negative serial markers and 9 hours of electrocardiographic monitoring in the ED, showed that stress testing had a negative predictive value of 98.7% for the diagnosis of ACS or cardiac event within 30 days. An abbreviated ED-based, so-called rule-out MI protocol, followed by mandatory stress testing, appears to be an effective diagnostic method for the detection of symptomatic CAD in low- to moderate-risk patients. Appropriate patient selection is vital, as is true in all diagnostic situations, to the correct application of this evaluation strategy. Current guidelines on exercise testing state that such testing can be performed when patients are free of active ischemic or heart failure symptoms for a minimum of 8 to 12 hours. Immediate stress testing without the rule-out MI evaluation, however, may be safe and cost-effective in patients with chest pain thought possibly to be of cardiac origin but with low suspicion of ACS. For determination of the safety and value of immediate exercise testing in the ED, previous studies were able to identify low-risk patients who underwent immediate exercise testing, with no adverse effects. Negative exercise test results were found in 64% of patients, all of whom were discharged home from the ED. The rate of CAD diagnosis or cardiac event within 30 days was 29% for the positive stress group, 13% for the nondiagnostic group, and 0.3% for the negative stress group. In this low-risk group of ED chest pain patients, 30-day follow-up revealed no mortality in any of the three groups. Graded exercise testing in the ED at most institutions is not available continuously. The mortality rate is extremely low (1/2500), but absolute contraindications include recent AMI (within 2 days), high-risk UA, uncontrolled cardiac dysrhythmias causing symptoms or hemodynamic compromise, symptomatic
Echocardiography

Two-dimensional echocardiography detects regional wall motion abnormalities associated with ACS due to the close correlation between wall motion and myocardial blood flow. Impaired myocardial contractility can range from hypokinesis to akinesia, with associated impaired myocardial relaxation during diastole. After AMI, paradoxical wall motion and decreased ejection fraction observed during systole indicate the subsequent loss of muscle tone from necrosis.

Particularly in individuals with nondiagnostic ECGs, the presence of regional systolic wall motion abnormalities in a patient without known CAD is a moderately accurate indicator of AMI or infarction, with a positive predictive accuracy of about 50%. When echocardiography is performed shortly after ED arrival, during an episode of chest pain, wall motion abnormalities have been detected in up to 90% of patients with ACS. The age of wall motion abnormalities, however, often cannot be determined without prior echocardiograms.

The absence of segmental abnormalities (presence of normal wall motion or diffuse abnormalities) has a significant high negative predictive value, as high as 98% for cases of suspected MI. Moreover, segmental wall motion abnormalities can be seen not only in the zone of acute infarction, but also in regions of ischemic stunning. Resting echocardiography provides an assessment of global and regional function, an important predictor of complications and mortality in patients with ACS. Prior studies have indicated that patients with mild and localized, as opposed to extensive, wall motion abnormalities have a low risk of ACS complications. In addition, echocardiography can help evaluate other causes of clinical presentations mimicking ACS, including valvular heart disease, aortic dissection, pericarditis, mitral valve prolapse, and pulmonary embolus. Finally, echocardiography is an important tool to assess for various complications of AMI, including acute mitral regurgitation, pericardial effusion, ventricular septal and free wall rupture, and intracardiac thrombus formation.

Technical limitations restrict the use of echocardiography in the ED. These include the quality of the study and expertise of the reader interpreting the study at the patient’s bedside. Injury involving more than 20% of the myocardial wall is required before segmental wall motion abnormalities can be detected echocardiographically. In addition, the inability of the two-dimensional echocardiogram to distinguish among ischemia, AMI, or old infarction and potential absence of wall motion abnormality in nontransmural infarctions can further limit the usefulness of two-dimensional echocardiography (Table 68.6).

Stress echocardiography, as opposed to resting echocardiography, can detect CAD and assess cardiac function early after an AMI. This can be performed with graded increases in cardiac workload by standardized exercise or pharmacologic adrenergic-stimulating agents, such as dobutamine. In addition, vasodilating agents, such as dipyridamole and adenosine, induce heterogeneous myocardial perfusion and reveal functional myocardial ischemia in susceptible patients. Stress echocardiography is superior to conventional treadmill testing for CAD in women. Graded dobutamine stress echocardiography assesses myocardial viability and ventricular function within the first few days after an AMI. Clinical studies of patients with nondiagnostic ECGs, negative markers, and negative rest echocardiography have suggested a role for emergency pharmacologic stress echocardiography as a provocative test after a period of observation with at least two marker and ECG assessments in a chest pain or ED observation unit.

Myocardial contrast echocardiography (MCE) uses microbubble ultrasonic contrast agents to assess microvascular perfusion and regional function with echocardiography. MCE evaluation of perfusion and regional function allows accurate risk stratification of ED patients with chest pain and nondiagnostic ECGs, even before serum markers are available. Smaller studies have reported low rates of adverse cardiac events in chest pain patients with normal MCE findings after a nondiagnostic ECG and negative serum markers. The clinical value of MCE in the ED, like that of resting and stress echocardiography, remains uncertain.

Myocardial Scintigraphy (Nuclear Imaging)

Radionuclide tracer injection and scintigraphy, such as with single-photon emission computed tomography (SPECT), allows real-time assessment of myocardial perfusion and function. Technetium-99 sestamibi has a slow redistribution to ischemic myocardium. This property allows immediate injection and imaging, which detects altered distribution consistent with some form of ischemic heart disease, followed by subsequent scanning, which provides more definitive data regarding the particular subtype of ACS. In patients with a normal initial study, the likelihood of ACS is extremely low. In patients with an initial study revealing abnormal distribution (ie, reduced uptake) of the tracer, some form of ischemic heart disease is likely. Subsequent imaging then reveals one of two patterns—normal redistribution (normal uptake) or continued reduced uptake. The redistribution pattern is consistent with active coronary ischemia, and continued reduced uptake is found in patients with MI, remote or recent. Myocardial scintigraphy has promising positive and negative predictive values for cardiac events, with high sensitivity and good specificity for CAD.

Immediate myocardial scintigraphy is useful for detecting ACS and the risk of cardiac events in patients in the ED with atypical chest pain, nondiagnostic ECGs, and low to moderate risk of AMI.

**Detection of wall motion abnormalities**

**Table 68.6**

**Emergency Department Bedside Echocardiography in Acute Coronary Syndrome—Pros and Cons**
Multiple studies have found a relatively high incidence of cardiac events, presence of AMI, and need for revascularization in patients with a positive nuclear scan. The probability of a cardiac event is tenfold higher in patients with abnormal scans than in patients with a normal scan. The incidence of cardiac events with a normal scan is lower than 1% for the 30-day period after the index study. Myocardial scintigraphy, if available, can reduce the number of patients admitted from the ED with chest pain who are ultimately determined not to have ACS, without reducing appropriate admissions for patients with ACS.

Myocardial scintigraphy, although accurate in establishing the diagnosis and useful in guiding therapeutic and further evaluation strategies, is not always available nor appropriate for use following the ED process of care for many reasons. Radioisotopes and the personnel to administer them may not be immediately available. Emergency clinician interpretation ability is not universal; particular expertise is required. Finally, myocardial scintigraphy of ED perfusion imaging are resting studies, rather than more provocative stress (exercise or pharmacologically induced) perfusion studies.

Coronary Computed Tomography Angiography

Coronary CT angiography (CCTA) imaging is a noninvasive modality to assess for coronary artery disease in the setting of the patient who has been ruled out for AMI and other active forms of ACS. This test has rapidly been gaining popularity as a valuable imaging study in this patient group. In a noninvasive fashion, CCTA provides information similar to that obtained from cardiac catheterization; cardiac catheterization, of course, is still considered the gold standard of cardiac imaging, but its position is being challenged by CCTA.

The emergency clinician must, however, understand the two basic applications of CT scanning in the patient with possible CAD, cardiac CT scanning and CCTA. Cardiac CT was introduced over 2 decades ago to screen for coronary calcium as a marker of underlying atherosclerotic heart disease and risk of ACS, largely in asymptomatic individuals. Whereas there are calcium scoring systems that assess cardiovascular disease risk, few studies have examined the role of standard cardiac CT in the assessment of patients with acute chest pain suspected of having experienced an ACS. Currently, standard cardiac CT is, at best, a screening tool for the presence of CAD and likely has little applicability in the ED.

The other modality of CT scanning in the patient suspected of CAD is coronary CT angiography, or CCTA. CCTA is used primarily in the evaluation of patients with acute chest pain and those with chronic chest pain; in both settings, the study is performed to assess for CAD. This imaging modality has potential application in the ED population for the patient with acute chest pain, most appropriately after some form of rule-out MI process, including serial assessments using examination, electrocardiography, and biomarkers. When considering the presence or absence of CAD, CCTA is accurate in the detection of coronary artery obstructive lesions. For example, in a large meta-analysis of appropriate studies, the accuracy for significant coronary artery obstructive lesions was very high, assuming that high-resolution, newer generation CT is used. Figs. 68.23A and B illustrate representative CCTA images demonstrating normal coronary anatomy; see Figs. 68.23C to E, which illustrate CCTA images with proximal left anterior descending (LAD) artery occlusion.

In symptomatic stable patients with low to intermediate pretest probability of CAD, CCTA is a very appropriate imaging study. CCTA is accurate, not only for the detection of significant coronary artery obstructive lesions but also the prediction of outcome. For example, a negative CCTA shows a very high negative predictive value of significant CAD and very low rate of a subsequent adverse event. In a multicenter study of patients seen in the ED with symptoms suggestive of ACS, the addition of CCTA into the evaluation strategy improved ED throughput, with a reduction in length of stay and reduced rate of admission. In this same study, an increase in outpatient testing was noted, ultimately resulting in no reduction in overall costs. A meta-analysis of four randomized controlled trials demonstrated similar findings, with reduced ED length of stay balanced by an increase in the use of invasive coronary angiography and revascularization.

The issue of radiation must also be considered in this study application. Newer testing CCTA modalities are associated with markedly lower doses of radiation. CCTA can be used with relatively smaller exposures to radiation, ranging from 2.0 to 5 mSv. For reference purposes, standard CT scanning and cardiac catheterization are associated with the following approximate radiation doses—9 mSv and 12 mSv, respectively.

Thus, in the ED population suspected of ACS, CCTA can be used in patients with low to intermediate suspicion for CAD after some form of ACS evaluation. This testing modality is accurate with respect to the identification of significant CAD and prediction of adverse events related to ischemic heart disease. The test requires significant expertise with respect to interpretation, whether by a radiologist or cardiologist. When used with newer testing modalities, it is associated with much lower radiation exposure. Although calcium scoring is not considered a useful testing modality in the ED population, calcium scoring may be considered when CCTA is performed. In general, a higher calcium presence in the coronary arteries is associated with less accuracy with the use of CCTA for the demonstration of significant CAD. CCTA can reduce ED evaluation time and admission rate at the expense of slightly greater use of additional, outpatient cardiac testing, such as cardiac catheterization.

Observation Unit Evaluation

The process of evaluation of the chest pain patient suspected of ACS occurs through three distinct phases of care (Fig. 68.24), including the STEMI recognition, rule-out ACS, and consideration of significant CAD. In the first phase, STEMI is the primary consideration; rapid performance of the 12-lead ECG is important so that STEMI is recognized with activation of appropriate ED- and hospital-based resources. The second phase is the traditional rule-out MI period, in which the patient is monitored clinically along with serial ECGs and serum markers. The evolution of STEMI as well as the diagnosis of NSTEMI and significant ACS will be made here. In the final phase of evaluation, the consideration of significant CAD is applied. Multiple appropriate pathways exist for this last goal. In fact, it can be accomplished in the ED or after ED discharge with outpatient follow-up. This last task can be accomplished during the initial ED presentation or later at follow-up; most appropriately, the stable patient is further evaluated after ED discharge by the primary care physician or consulting cardiologist on an outpatient basis. Unstable patients or patients with concerning findings during the ED evaluation should be considered for admission to the hospital for further care.

This process of care can occur in the ED or an ED-based observation unit. The concept of an observation unit can be a physical location with a specified area of the ED or a virtual concept with its abilities applied anywhere in the ED with appropriate monitoring and treatment capability.

Specialized units for the lower risk population are used in one-third of EDs in the United States. The goal of the chest pain center (CPC) is to provide an integrated approach to patients with chest pain or potential ACS that includes rapid triage, early identification, evaluation, and treatment of low-risk ACS patients. Guidelines and clinical pathways play an essential role in the CPC
A CPC protocol should rapidly direct patients with possible ACS into an appropriate treatment area where electrocardiography and a clinical examination can be performed within the first 10 minutes. Patients with STEMI who require immediate reperfusion therapy, with UA who need further intervention, or are experiencing other cardiorespiratory complications of ACS can be identified quickly. This goal can be combined with an efficient ED evaluation of patients with a low to moderate risk of ACS. The greatest medical benefit from the CPC is the early identification of patients with ACS, particularly STEMI; the most significant financial impact is the reduction of low-yield hospital admissions.

There are multiple CPC models, but all emphasize expedited assessment and initiation of ACS care. The benefit of this standardization is magnified when we look at time-sensitive care, such as a target door to drug time of less than 30 minutes or a door to balloon time of less than 90 minutes (where percutaneous...
procedures are available) for patients with typical and uncomplicated presentations of STEMI. The CPC may have assigned nursing personnel who rapidly evaluate the patient with chest pain with a 12-lead ECG, as well as screening vital signs and cardiac monitoring, and deliver the ECG directly to an emergency clinician capable of making a decision about activation of the catheterization laboratory or administration of fibrinolytic therapy.

The CPC may also be used as an observation and evaluation unit where patients with chest pain and a low to intermediate clinical likelihood of ACS can be monitored with electrocardiography, ST segment trending, serial 12-lead ECGs, and sequential serum markers. In addition, many CPCs now use further ACS evaluation with stress testing, echocardiography, or myocardial scintigraphy before disposition. Significant cost savings occur through the expedited evaluations and avoidance of unnecessary admissions, with typical charges and actual costs ranging from 20% to 50% of the costs for the usual inpatient approach. Previous studies have prospectively compared a CPC with the traditional hospital admission to rule out MI and showed a reduction in hospital admissions by almost 50%, with no adverse events in CPC patients with a negative stress test.

A chest pain–accelerated diagnostic protocol approach to low-to intermediate-risk patients can be feasible, safe, and effective. Many accelerated diagnostic protocols have been validated to shorten the length of ED evaluation needed in the lower risk patient populations and, as troponin assays have increased in sensitivity, the length of time of serial testing has decreased dramatically in these protocols. The HEART Pathway Randomized Trial has demonstrated that the use of a clinical decision tool—the HEART score—plus troponin measurements at 0 and 3 hours was safe and effective in ACS evaluation in patients presenting to the ED with ACS-associated symptoms without ST elevation on the ECG. The HEART Pathway has demonstrated shortened length of stays, increased early discharges, a trend toward decreased objective cardiac testing at 30 days, and no adverse cardiac events in the early discharge group at 30 days of follow-up.39

Approximately 80% of patients with chest pain can be safely evaluated in the ED with ultimate discharge to home. The resources required for a successful CPC-based operation, in which patients undergo rapid exclusion of ACS through serial testing, continuous monitoring, and immediate provocative stress testing, are considerable. Although studies have suggested that CPCs decrease the number of admissions, they may increase the number of patients seen in the ED for chest pain, and emergency clinicians may overuse the CPC-accelerated diagnostic protocol approach in patients whom they would otherwise have discharged.

**MANAGEMENT**

An understanding of the pathophysiology of ACS allows the emergency clinician to select the most appropriate therapies for the ACS patient. ACS pathophysiology includes the following: (1) endothelial damage through plaque disruption, irregular luminal lesions, and shear injury; (2) platelet aggregation; (3) thrombus formation causing partial or total lumen occlusion; (4) coronary artery vasospasm; and (5) reperfusion injury caused by oxygen free radicals, calcium, and neutrophils. In patients with noninfarction ACS, spontaneous fibrinolysis of the thrombus occurs rapidly, minimizing ischemic insult; persistence of the occlusive thrombus, however, often results in more serious forms of ACS, including NSTEMI and STEMI.

**Time-Sensitive Nature of Acute Coronary Syndrome Therapy**

Early patency resulting in myocardial salvage is the key benefit of emergent reperfusion therapy, using fibrinolysis or PCI. Timely treatment within the first hours after symptom onset may result in substantial, if not complete, myocardial salvage. Delivered later, from 2 to 12 hours after STEMI onset, treatment may result in a more modest, but significant, benefit. The opening of the occluded artery causes less adverse ventricular modeling, reduces occurrence of ventricular aneurysm, increases blood flow to the myocardium, and improves electrophysiologic stability. It has been well established that preserved left ventricular function and mortality at the 24-hour and 30-day endpoints are directly related to angiographic patency at 90 minutes. The relationship between rapid revascularization and mortality has been clearly demonstrated, and it has been shown that with each additional 30 minutes of delay to PCI, the relative 12-month mortality risk increases by 7.5%. Fig. 68.25 depicts the relationship between time to reperfusion and benefit in STEMI.

Prehospital delay factors occur from the time the patient decides to seek medical attention until the patient arrives at the ED. It is not uncommon for patients to delay treatment significantly by calling their primary care physician, attempting to transport themselves or waiting for transport by other nonmedical professionals. For slightly less than 50% of patients with suspected AMI, the EMS system is the point of first medical contact.40 Wide variations in the availability of EMS systems and their varied levels of integration into their local ED and hospital ACS identification and evaluation processes can further complicate and delay care. EMS system resource is related to patient care ability; in systems with advanced and robust local resource, very comprehensive state of the art care is possible.

**TIME TO REPERFUSION VERSUS DEGREE OF BENEFIT**

![Fig. 68.25. Relationship between time to reperfusion and benefit STEMI](image-url)

Further delays can occur between the time a patient arrives at the hospital and initiation of acute revascularization therapy. Although studies have shown that the average time to fibrinolysis ranges from 45 to 90 minutes, the AHA recommends that all patients with STEMI receive fibrinolytic therapy within 30 minutes of arrival or undergo primary PCI (ie, device across the culprit artery) no later than 90 minutes after arrival.⁶

STEMI patients who receive hospital-based reperfusion therapies (eg, fibrinolytic agent, PCI) progress through a sequence of critical steps that can define process time points. Within each interval, various impediments to timely care can occur. Reducing delay times is applicable to all time points in the ED by addressing the four Ds: door (events before arrival at the ED), data (obtaining the ECG), decision (arriving at the STEMI diagnosis and deciding on therapy), and drug (administering the fibrinolytic agent or passing the angioplasty catheter across the culprit lesion for PCI candidates).⁴²⁻⁴⁶

Prehospital notification to the ED of the impending arrival of a patient with a suspected STEMI, particularly when ST segment elevation is suspected, has become standard practice in many established EMS systems. A field 12-lead ECG may assist in diagnosis and decrease the reperfusion time by initiating the hospital-based sequence of necessary events to occur in parallel, as opposed to serially. Some systems have been able to bypass the ED in selected prehospital notifications of STEMI, and these patients go directly from the ambulance to the CCL for PCI. Although these systems have shown significant decreases in door to reperfusion times, however, they were unable to demonstrate any improvement in clinical outcomes, including mortality.⁴³⁻⁴⁵

Self-transported patients with possible ACS should be evaluated by the triage nurse immediately and an ECG acquired within 5 to 10 minutes of arrival. The development of hospital-based protocols and system response plans for identifying and rapidly treating patients reduces the amount of time to treatment. When using fibrinolysis in uncomplicated cases, the emergency clinician should activate the hospital-based system for reperfusion. Checklists of inclusion and exclusion criteria for fibrinolytic therapy should be available, and those fibrinolytic agents should be stored and administered in the ED. In a system in which fibrinolysis is the sole reperfusion therapy, the decision to administer that therapy rests solely with the emergency clinician. Nonconsultative communications with family physicians, internists, or cardiologists before administration of the agent may result in unnecessary delays. Consultative discussions should only be required in complicated situations before the administration of therapy.

If the hospital offers primary PCI, many hospitals activate so-called STEMI alert responses when an STEMI patient is identified prehospital or in the ED. Analogous to the trauma alert, the cardiologist and catheterization laboratory personnel are immediately mobilized. Prehospital or emergency clinician activation of the catheterization laboratory demonstrates very high rates of accurate STEMI diagnosis, with very low rates of false activation (ie, the STEMI mimicker) while markedly reducing the time to definitive therapy.⁴³⁻⁴⁶ Interhospital transfer of STEMI patients for PCI when they are also candidates for fibrinolysis should be discouraged if definitive therapy (ie, catheter placement across the culprit lesion) is likely to be delayed beyond 120 minutes, except in cases of hemodynamic shock (see later) or in patients for whom fibrinolysis is contraindicated.⁷

**Pharmacologic Intervention**

A range of medications can be used in the patient with ACS (Table 68.7). These agents range from the basic to the complex, including oxygen, IV fluids, antiplatelet and anticoagulant agents, nitrroglycerin, opioid analogesics, β-adrenergic blocking agents, and fibrinolytic agents.

Oxygen

Oxygen is considered a medication, a medication with significant potential to benefit and harm the patient with ACS. A brief mention of the most appropriate strategy for oxygen treatment in the ACS patient is warranted. Respiratory compromise can occur during ACS, usually as a result of acute pulmonary edema or chronic pulmonary disease. Suspected ACS patients with respiratory distress, demonstrated by physical examination and/or oxygen saturations, should receive supplemental oxygen as standard therapy. The rationale for this standard oxygen therapy is that maximization of oxygen saturation may improve the delivery of oxygen to the tissues and thus reduce the ischemic process and related negative outcomes.

There is limited evidence regarding the use of supplemental oxygen therapy in the suspected ACS patient with normal oxygen saturation and no other evidence of respiratory compromise. The practice of administering oxygen to all patients, regardless of their oxygen saturation, is based on rational conjecture and research performed prior to the current reperfusion era in acute coronary care. More recent studies of this issue are limited but have suggested that excessive oxygen therapy can increase the rate of adverse outcome in the ACS patient, particularly involving STEMI. Hyperoxia, developing as a result of excessive supplemental oxygen therapy, can potentiate coronary vasoconstriction and increase oxidative stress, worsening outcome in these patients.

Recently, the AVOID trial demonstrated that oxygen therapy, delivered to patients suspected of STEMI who also had normal oxygen saturations and no other evidence of respiratory compromise, likely increased early myocardial injury and was associated with a larger size of the infarction. Furthermore, re-infarction and cardiac dysrhythmia were also increased in the oxygen therapy group. In other patient groups, such as resuscitated cardiac arrest patients, hyperoxia has been associated with worse outcomes as compared with normoxia.

Thus, in suspected or confirmed ACS patients, supplemental oxygen therapy is appropriate for patients demonstrating respiratory compromise, noted by physical examination or oxygen saturations less than 94%. Conversely, in patients without respiratory compromise, oxygen therapy can be withheld.

Nitroglycerin

Nitroglycerin decreases myocardial preload and, to a lesser extent, afterload. Nitroglycerin increases venous capacitance and induces venous pooling, which decreases preload and myocardial oxygen demand. Direct vasodilation of coronary arteries may increase collateral blood flow to the ischemic myocardium. Nitroglycerin has been used for decades in patients with suspected or known ACS. Most studies of IV NTG in the setting of ACS, however, are from the prefibrinolytic era. Although the data from multiple trials originally noted a 35% mortality reduction with IV NTG in the setting of AMI, this study preceded the modern era of aggressive reperfusion therapies coupled with potent anticoagulant and antiplatelet agents. No contemporary evidence (ie, in the reperfusion era of acute cardiac care) has shown improved outcomes with the routine use of any form of nitrate therapy in patients with AMI. In the ACS patient, it must be noted that the use of NTG in any formulation is another management option, yet its use is not mandatory. In situations in which hypoperfusion is present or is anticipated to occur, it is very appropriate to withhold NTG in all formulations.

Patients with possible ACS and a systolic blood pressure greater than 90 mm Hg can receive a sublingual NTG tablet (0.4 mg [400 µg]) on presentation. If symptoms and pain are not fully relieved with three sublingual tablets, IV NTG can be considered. With bradycardia, hypotension, inferior wall STEMI, and right ventricular infarction, a sudden decrease in preload associated with NTG can result in profound hypotension. An initial infusion rate of 10 µg/min is titrated to pain symptoms. The emergency clinician can increase the infusion at regular intervals, allowing a 10% reduction in the mean arterial pressure if the patient is normotensive and a 20% to 30% reduction if hypertensive.

Morphine and Other Opioid Analgesic Agents

Morphine is a potent opioid analgesic with weak sympathetic blockade, systemic histamine release, and anxiolysis. If a patient with possible ACS is unresponsive to NTG or has recurrent symptoms despite maximal antiischemic therapy, administration of morphine sulfate is a reasonable analgesic. The relief of pain and anxiety decreases oxygen consumption and myocardial work. Some vasodilatory effects are also noted with preload reduction. Standard doses of morphine sulfate are 2 to 4 mg IV, repeated every 5 to 30 minutes as necessary. Caution is advised with morphine use in this setting. Although appropriate, it must be remembered that morphine is a potent medication with significant vasodilatory effects and profound sedation, with respiratory depression. In addition to allergic reactions, the most significant adverse effect of morphine sulfate administration is hypotension, which is managed with IV crystalloid as a bolus. Its use in modest amounts is reasonable. In addition to its analgesic properties, it is also an anxiolytic agent, a valuable feature in certain ACS patients. Withholding morphine and other analgesic agents is not appropriate if the emergency clinician is concerned about the potential for iatrogenic hypoperfusion, sedation, or respiratory depression.

Other opioid agents, such as fentanyl, are reasonable for use in the ACS patient. The same caveats and general recommendations apply with other opioid agent administration in the ACS patient.

β-Adrenergic Blockers

Historically, β-adrenergic blocking agents have been effective in ameliorating catecholamine-induced tachycardia, including ventricular fibrillation, increased contractility, and heightened myocardial oxygen demand during the infarction period. Although beta blockade was shown to decrease mortality for patients with AMI, these observations occurred when adjunctive therapies were few and β-adrenergic blockade was essentially monotherapy in AMI. Contemporary management strategies include highly effective reperfusion therapies coupled with potent anticoagulant and antiplatelet agents; thus, their widespread use must be reconsidered.

Multiple studies have suggested that the widespread intravenous use of β-adrenergic blockade should be reconsidered. The use of the early IV β-adrenergic blocking agents in these studies was associated with higher rates of death, heart failure, cardiogenic shock, recurrent ischemia, and pacemaker use as compared to patients who received early oral administration. These increases occurred despite the exclusion of patients with obvious contraindications, including preexisting hypotension, bradycardia, or heart failure. Large studies followed that evaluated patients with suspected STEMI, comparing early IV β-adrenergic blocking agent use followed by continued oral therapy versus placebo. These studies found no significant difference between the two groups in terms of mortality; however, the group receiving β-adrenergic blockers demonstrated a minimal reduction of re-infarction and ventricular fibrillation. This was at the expense of a significantly higher rate of cardiogenic shock and increased rates of development of heart failure requiring treatment, persistent hypotension, and bradycardia.

The early IV use of β-adrenergic blocking agents, when coupled with contemporary therapy in the setting of ACS, does not appear
to offer significant benefit and is associated with an increased rate of adverse events. Therefore, their IVs use in the ED in the ACS patient is discouraged. Conversely, oral administration to ACS patients without contraindications during the first 24 hours of management is a class I recommendation from the ACC/AHA and can be accomplished after admission has occurred. This strategy allows for stabilization of the patient while additional clinical data are obtained to determine appropriateness of this therapy. Empirical therapy in the ED, however, should be reserved for only those patients who have adverse effects from significantly elevated blood pressure or significant tachydysrhythmia, despite application of other appropriate medications.

Angiotensin-Converting Enzyme Inhibitors

Angiotensin–converting enzyme (ACE) inhibitor agents benefit patients with CHF. ACE inhibitors may also reduce morbidity and mortality after AMI. In particular, patients treated with ACE inhibitors experience a reduction in cardiovascular mortality, decreased rates of significant CHF, and fewer recurrent AMIs. These benefits increase when ACE inhibitors are used in conjunction with other agents, such as aspirin and fibrinolytic agents. The mechanism of action regarding a reduction in recurrent AMI is unknown but may involve a reduction in plaque rupture related to decreased intracoronary shear force or neurohumoral influences. Therapy should be initiated within the first 24 hours following an ACS event, although ED administration is not indicated.

HMG–Coenzyme A Reductase Inhibitors (Statins)

A number of investigations have demonstrated a reduction in inflammation and reinfarction, angina, and lethal arrhythmia with the administration of statin drugs in the first few days after an ACS event. Although there is no indication for statin therapy in the ED management of ACS, initiation of this therapy should occur within the first 24 hours or should continue if patients are already undergoing statin therapy, because discontinuation during hospitalization is associated with an increase in near-term mortality and adverse events. The administration of statin therapy before elective or urgent PCI for ACS is reasonable to decrease the incidence of a periprocedural AMI; however, there are no specific risk or safety data regarding its use in this setting.

Calcium Channel Blockade

As with beta blockade, the primary benefit of calcium channel blockers appears to be in regard to symptom resolution. Unfortunately, these agents may be accompanied by a significant vasodilatory effect, resulting in hypotension and potentiation of the coronary ischemic process. Like beta blockers, calcium channel blockers have a substantial negative inotropic effect. AV nodal blockade is also a significant side effect that may be exacerbated in patients previously treated with beta blockers or with ischemia-related conduction disturbance. Unless specifically used for rate control of supraventricular dysrhythmia in a patient who cannot tolerate beta blockade, calcium channel blocker agents have no role in the ED management of ACS.

Antiplatelet Therapy

In non-AMI ACS patients (ie, unstable angina), dramatic reductions in the progression to acute infarction are noted with appropriate antiplatelet therapy. The administration of antiplatelet therapy, particularly aspirin, is indicated in the ED for most ACS patients. For AMI, the administration of aspirin and other antiplatelet agents is associated with significant reductions in mortality, ranging from 25% to 50%.

**Aspirin.** Aspirin, the prototypical antiplatelet agent, is the most cost-effective treatment in ACS care. It irreversibly acetylates platelet cyclooxygenase, thereby removing all activity for the life span of the platelet (8–10 days). Thus, aspirin stops the production of proaggregatory thromboxane A2 and is an indirect antithrombotic agent. Aspirin also has important nonplatelet effects because it inactivates cyclooxygenase in the vascular endothelium, thereby diminishing the formation of antiaggregatory prostacyclin.

It is well established and accepted that aspirin independently reduces the mortality of patients with AMI without fibrinolytic therapy (overall 23% reduction) and is synergistic when used with fibrinolytic therapy (42% reduction in mortality). The usual dose is 324 mg of non–enteric-coated aspirin, chewed and swallowed. Enteric-coated aspirin should be avoided in the acute setting of ACS due to delays in the onset of antiplatelet activity. The administration of aspirin in the ED is strongly recommended immediately on identification of any patient with suspected ACS, either UA or AMI. It should be administered to all such patients unless significant allergy, hemorrhage, or other issues, such as a potential aortic dissection, contraindicates its use. More recent studies have established that lower dose aspirin (<162 mg) appears to be as effective as higher dose aspirin (>162 mg) at preventing adverse cardiac events, with fewer bleeding risks. These findings were consistent when given alone or with other antiplatelet agents (eg, clopidogrel).

**Glycoprotein Iib/Illa Receptor Inhibitors.** Glycoprotein Iib/Illa receptor inhibitors (GPIs) are potent antiplatelet agents; they include abciximab, eptifibatide, and tirofiban. GPIs, however, demonstrate clinical usefulness in only a subset of ACS patients, those undergoing PCI as a reperfusion strategy. Therefore, the primary indication regarding GPI administration is planned mechanical coronary intervention. Furthermore, the largest studies on GPI administration timing have not shown outcome benefit to upstream use in the ED when compared to catheterization laboratory administration. Currently, there is no clear indication for the ED administration of GPIs unless other antiplatelet agents are not tolerated or unavailable. This class of medications is not standardized in the ED setting, and other antiplatelet agents (PS123 receptor inhibitors) are preferred for upstream administration in the care of ACS.

Numerous trials have demonstrated the effectiveness of these agents in the subset of ACS patients who are managed with PCI, with or without an intracoronary stent. These trials have consistently shown reduced mortality, need for subsequent revascularization, and recurrent ischemia, although at the cost of an increase in hemorrhagic complications.

Multiple studies evaluating GPI use in ACS patients have concluded that patients who undergo PCI benefit markedly from GPI administration. In ACS patients managed medically, without mechanical revascularization, consistent benefit with GPI therapy is not found with the use of direct outcome measures or secondary markers of successful reperfusion, and hemorrhagic complications are increased.

The benefits of GPI therapy were established mainly before the development of contemporary invasive strategies, raising questions about the timing (ie, upstream initiation in the ED) when combined with other antiplatelet therapies. Although initially small preliminary studies have shown promise for upstream GPI administration, larger trials have not supported their routine use in the ED. Evidence supports a highly selective strategy for the use of GPIs that balances ACS risk in the treatment of a patient with dual-agent platelet inhibition and planned PCI versus the potential bleeding risk. GPIs consistently demonstrate benefit in ACS patients treated with urgent mechanical revascularization; in other groups of ACS patients, such as medically managed patients,
PSY$_{12}$ Receptor Inhibitor Agents. The thienopyridines ticlopidine, clopidogrel, and prasugrel are more potent platelet inhibitors than aspirin. They inhibit the transformation of the PSY$_{12}$ receptor into its high-affinity ligand-binding state, irreversibly inhibiting platelet aggregation for the duration of the life of the platelet. Ticlopidine has nonlinear kinetics and, with repeated administration, reaches a maximal effect after 8 to 11 days of use. Clopidogrel, a ticlopidine analogue, and prasugrel have the advantage of a rapid onset of action.

Clopidogrel has traditionally been the preferred ED agent of this class due to its relatively rapid onset of action, improved safety profile, and proven efficacy when given upstream and in association with thrombolytic therapy. Prasugrel incurs a higher bleeding risk than clopidogrel, in patients older than 75 years, those who weigh more than 60 kg, those who have had a previous transient ischemic attack (TIA) or stroke, and those at high risk for bleeding. The ACCOAST trial showed no improvement in outcomes for patients treated with prasugrel in the ED versus dosing at the time of PCI. Because of this and other similar studies, prasugrel is not recommended for upstream use in the ED in ACS patients. Ticlopidine is associated with a risk of neutropenia, thrombotic thrombocytopenic purpura, and agranulocytosis; furthermore, it demonstrates a much slower onset of platelet inhibition. With clopidogrel, maximal platelet inhibition occurs after 3 to 5 days of clopidogrel therapy with 75 mg daily; an earlier onset of platelet inhibition is seen when a higher loading dose is used (300–600 mg). For example, there is clear benefit to clopidogrel administration (300 mg loading dose) at least 6 hours before PCI in patients with STEMI; higher doses (eg, 600 mg) demonstrate a trend toward improvement at slightly earlier time periods (ie, 3–4 hours).

Ticagrelor, a nucleoside analogue, also acts as a PSY$_{12}$ receptor inhibitor, however, via a different mechanism not requiring hepatic activation. It is rapidly absorbed, reaching peak serum concentration at 2.5 hours. Clinical data have demonstrated that ACS patients given ticagrelor were less likely to die from cardiovascular causes, but these improved outcomes are tempered by higher rates of nonprocedure-related bleeding, including more frequent fatal intracranial hemorrhage when compared with clopidogrel administration. Further analysis of the PLATO study has assessed the increased cost of ticagrelor versus clopidogrel when combined with aspirin and determined that with the increased life expectancy, ticagrelor plus aspirin is a “good value for the money.”

Cangrelor, an IV PSY$_{12}$ receptor inhibitor, has potential for significant therapeutic advantages over the other drugs in this class due to its immediate onset of antiplatelet activity and very short half-life. It is administered IV in its active form (unlike clopidogrel), not as a prodrug requiring metabolism prior to its onset of action. Unlike the oral drugs in this class, which that require 2 to 6 hours to reach active levels, cangrelor is active immediately on injection. This has potential benefits in patients who are undergoing rapid PCI—specifically, the STEMI population with an invasive management plan. Cangrelor also has a very short half-life (4–6 minutes), which makes the treatment of potential CABG patients with a PSY$_{12}$ receptor inhibitor possible up until the time of surgery. Initial studies have shown the ability to maintain low levels of platelet activity in the presurgery time period on cangrelor, compared to the recommended 5 days off of medication with the oral PSY$_{12}$ receptor inhibitors, without an increase in major bleeding in CABG patients. Cangrelor also appears to have the potential for improved outcomes in patients undergoing PCI when compared to current antiplatelet therapy.

The drug is currently seeking US Food and Drug Administration (FDA) approval, after rejection in 2014 due to mixed results in previous clinical trials. Cangrelor received a favorable vote for limited indications from the FDA in April 2015 and may be available for clinical use in the near future.

In accordance with the 2013 AHA Guidelines for STEMI management, patients should receive a loading dose of clopidogrel or ticagrelor in addition to standard ACS care (ASA, anticoagulants, and reperfusion therapy), assuming there are no contraindications to its use, prior to PCI (upstream). For patients with definite or likely NSTEMI, in accordance with the 2014 AHA guidelines for NSTEMI management, the administration of a PSY$_{12}$ receptor inhibitor should also be initiated upstream in the ED prior to PCI.

Another indication for the ED administration of clopidogrel is the patient with a high-risk ACS presentation who is truly allergic to ASA (ACC/AHA class I indication). This high-risk presentation would be characterized by objective clinical abnormality, including a significantly abnormal serum marker or 12-lead ECG. Considerations include the ultimate treatment strategy chosen (ie, medical vs. invasive) and the time to angiography if an invasive plan is selected. ACS patients managed medically (ie, noninvasively) or invasively with coronary angiography deferred to a later time are the most appropriate potential candidates for clopidogrel. In the patient selected for invasive management, the time to the procedure is a primary issue in considering clopidogrel; patients undergoing early angiography, within 6 hours, are less likely to derive significant benefit, whereas deferred catheterization likely will gain advantage.

In the patient with UA or NSTEMI, clinical benefit is confirmed in UA patients when treated with clopidogrel in a noninvasive strategy scenario, with an increase in the incidence of major hemorrhage. As noted, invasively managed patients receiving the drug with less time to procedure performance do not benefit from such treatment. The NSTEMI patient demonstrates improved outcome with clopidogrel therapy when a conservative treatment scenario is initially followed. Of note, a large portion of these patients will undergo PCI within the first 24 hours after admission; however, this so-called delayed PCI allows for benefit to occur from clopidogrel administered earlier in the course of management.

The STEMI patient who is managed medically (ie, with a fibrinolytic agent) will also benefit from clopidogrel use. Clopidogrel therapy in conjunction with fibrinolysis, followed by deferred cardiac catheterization occurring at least 2 days after AMI—clearly beyond the 6-hour window—decreases the rates of death, recurrent ACS, and urgent coronary revascularization. This improvement occurs without a significant increase in hemorrhage.

The potential need for urgent CABG should also be strongly considered. The higher risk ACS patient will more likely benefit from PSY$_{12}$ receptor inhibitor therapy, but that same patient is also more likely to need urgent CABG. It is not possible, however, to identify ACS patients requiring urgent CABG reliably. Previous registries have shown that as many as 14% of ACS patients will undergo CABG, a reasonably frequent rate of surgical intervention; most centers, however, report a 2% to 5% incidence of coronary surgery. Reviews of ED ACS patients have been unable to demonstrate one or a combination of clinical features apparent in the ED that reliably identify patients not requiring CABG. It is interesting and important to note that although these CABG patients had a greater incidence of bleeding perioperatively, outcomes were not statistically different in clopidogrel versus placebo groups in this surgical subset. It is likely that as the cardiovascular surgeon gains more experience with PSY$_{12}$ receptor inhibitor administration, and as other alternatives such as cangrelor become available for perioperative therapy in the CABG patient, this concern will continue to decrease.

The ACC and AHA have suggested, in the form of a class I recommendation, that clopidogrel or ticagrelor should be
Antithrombins

As with antiplatelet therapies in ACS patients, significant reductions in the progression to acute, recurrent, or extensive infarction and death are noted in individuals treated with aggressive antithrombin therapy. There are currently four options for antithrombin therapy in the setting of ACS, including unfractionated heparin (UFH), LMWH, direct thrombin inhibitors (bivalirudin), and factor Xa inhibitors (fondaparinux). Antithrombotic therapy is indicated for ACS patients with recurrent anginal pain, AMI (NSTEMI and STEMI), a significantly positive serum marker, and a dynamic 12-lead ECG.

Heparins. The term heparin refers not to a single structure but to a family of mucopolysaccharide chains of varying lengths and composition—hence, unfractionated—with pronounced antithrombotic properties. At standard doses, UFH binds to antithrombin III, forming a complex that is able to inactivate factor II (thrombin) and activate factor X. This prevents the conversion of fibrinogen to fibrin, thus preventing clot formation. Heparin by itself has no anticoagulant property. This indirect effect on thrombin inhibits clot propagation; it prevents heparin, however, from having any effect on bound thrombin in a thrombus. UFH also assists in the inactivation of factors Xla and IXa through antithrombin and interacts with platelets.

UFH has a profound synergistic effect with aspirin in preventing death, AMI, and refractory angina in ACS patients, particularly those with AMI and, to a lesser extent, high-risk UA. UFH should be administered early in patients with the following ACS features: recurrent or persistent chest pain, AMI, positive serum marker, and a dynamic ECG. In patients receiving thrombolytic therapy and UFH, it has been shown that bleeding and mortality were higher in patients receiving an 80-unit/kg bolus and 18-unit/kg infusion compared with patients with a lower bolus amount and infusion rate. Therefore, the weight-adjusted regimen recommended for UFH in the setting of a STEMI receiving thrombolytic therapy or non-ST elevation ACS patients is an initial bolus of 60 units/kg (maximum, 4000 units) and an initial infusion of 12 units/kg/hr with an activated partial thromboplastin time goal of 1.5 to 2.5 times the control value. The weight-adjusted regimen UFH in STEMI patients receiving PCI is dependent on the planned use of a GPI during PCI. If GPI use is planned during PCI, the bolus dose should be 50 to 70 units/kg (no maximum dose) and, if no GPI use is planned, the bolus dose should be 70 to 100 units/kg (no maximum dose). LMWHs constitute approximately one-third of the molecular weight of heparin and are less heterogeneous in size. LMWHs inhibit the coagulation system in a fashion similar to that of UFH. Approximately one-third of the heparin molecules bind to antithrombin III and thrombin. The remaining molecules bind only to factor Xa. The variable efficacy found among the LMWHs is attributed to different ratios of antifactor Xa to antifactor IIa. High-ratio preparations have a clear advantage over standard heparin; enoxaparin has the highest ratio of available LMWHs. LMWH was designed on the basis of the hypothesis that the inhibition of earlier steps in the blood coagulation system would be associated with a more potent antithrombotic effect than inhibition of subsequent steps. This results from the amplification process inherent in the coagulation cascade—that is, a single factor Xa molecule can lead to the generation of multiple thrombin molecules.

Potential advantages of LMWH over UFH include easier administration, greater bioavailability, more consistent therapeutic response among patients, and longer serum half-life, producing a more manageable administration schedule, albeit at a higher cost. The combination of aspirin, beta blocker, and LMWH significantly decreases the rate of nonfatal AMI or death at 1 in the first several weeks after treatment but has much less pronounced impact out to multiple months. Studies comparing outcomes between LMWH and UFH have shown mixed results; some show better outcomes with LMWH, but others do not. In summary, the LMWH enoxaparin demonstrates some degree of benefit compared with UFH in patients at higher risk for non–ST segment elevation ACS who are treated conservatively without immediate PCI (ie, beyond 24 hours). For STEMI patients managed aggressively with rapid PCI, UFH is preferred over enoxaparin.

Enoxaparin is administered in a twice-daily regimen subcutaneously at a dose of 1 mg/kg for all ACS patients. If patients have renal dysfunction, with an estimated glomerular filtration rate of less than 30 mL/min, the dose should be reduced to 1 mg/kg in a single daily administration. Few safety data are available for enoxaparin in ACS patients with renal insufficiency, and UFH may be preferable.

Contraindications to heparin therapy include known allergy, active ongoing hemorrhage, and predisposition to such hemorrhage. Furthermore, patients who have their heparin therapy changed (UFH to LMWH and vice versa) during the active treatment phase of their ACS care experience higher rates of bleeding.

Most patients with AMI require therapy with heparin, whether it is fractionated or unfractionated. Non-AMI ACS, however, is an entirely different issue because UA is a heterogeneous condition. Only high-risk UA patients (recurrent or continued pain, or new ischemic electrocardiographic changes) should be considered for heparin therapy. For example, the stable patient with a classic description of new-onset angina, who is sensation-free with a negative serum marker and normal ECG, is still correctly diagnosed with UA. In contrast, an individual with ongoing pain, intermittent or constant, with a dynamic ECG clearly is experiencing an active, unstable coronary event. The latter patient, who is at higher risk, can benefit from heparin therapy more than the former. Heparin therapy, however, can be a major contributor to morbidity and mortality among hospitalized patients. Major bleeding develops in 1 of every 90 patients treated, and heparin-induced thrombocytopenia in 1 of 34 patients. LMWH is as effective as UFH in patients with non–ST segment elevation ACS and does not greatly increase the bleeding risk while decreasing the risk of thrombocytopenia.

Other Antithrombins: Bivalirudin, Fondaparinux, and Hirudin. The direct thrombin inhibitor bivalirudin is a potent antithrombin anticoagulant providing significant theoretical advantages compared with heparin. Bivalirudin is a bifunctional 20-amino acid peptide designed on the basis of the structure of hirudin. It has properties similar to those of hirudin but also interacts with the catalytic site of thrombin. Bivalirudin, however, is more effective than heparin in reducing death or reinfarction in patients with ACS, particularly those patients undergoing very early PCI.

Bivalirudin, compared with heparin, produces similar rates of ischemia and major bleeding at 1 month. Bivalirudin when used with clopidogrel is comparable to the combination of...

heparin and GPI before coronary angiography or PCI. When used alone, it is inferior to the combination of heparin and GPI. Bivalirudin should be considered an acceptable alternative anticoagulant agent compared with the UFH in the STEMI patient undergoing PCI.5-7

Fondaparinux is a synthetic oligosaccharide with a structure similar to the heparins. It is the first widely used selective factor Xa inhibitor. With the increased emphasis on the reduction of hemorrhagic complications in ACS care, this drug may be considered as a reasonable alternative to UFH in the care of NSTE MI patient receiving non-invasive management; however, the increased risk of catheter-associated thrombi during PCI prevents its use without additional UFH administration when an invasive strategy is chosen.

In previous comparison studies, fondaparinux was found to be similar to enoxaparin in the short-term reduction of ischemic events, yet substantially reduced major bleeding and improved long-term outcome. When the use of fondaparinux was reviewed in STEMI patients managed medically with streptokinase, it was found that fondaparinux significantly reduced hemorrhage as well as death and MI when compared to UFH and LMWH. As a result, fondaparinux has a class 1 AHA recommendation as an alternative to UFH and LMWH in NSTE MI and STEMI patients that are not undergoing PCI.5-6

Hirudin is a peptide derived from the leech salivary gland but was also synthesized as recombinant hirudin. It binds directly with high affinity to thrombin and can inactivate thrombin already bound to fibrin (clot-bound thrombin) more effectively than UFH. Hirudin does not require endogenous cofactors, such as antithrombin III, for its activity. Also, unlike heparin, hirudin can inhibit thrombin-induced platelet aggregation. Hirudin has demonstrated little significant benefit over other anticoagulants in ACS, with a possibly increased rate of hemorrhage; thus, its pharmaceutical production was discontinued in 2012.

Reperfusion Therapies

Rapidly reestablishing perfusion in the infarct-related coronary artery with the use of fibrinolytic therapy or PCI increases the opportunity for myocardial salvage, with resultant reductions in mortality and improvements in quality of life post-MI. Pharmacologic and mechanical methods of reperfusion are both effective under specific clinical conditions. More than 2 decades ago, the importance of early coronary artery patency was recognized, and it was demonstrated that 90-minute patency predicts improved rates of survival and preserves left ventricular function.

Fibrinolytic therapy unequivocally improves survival in patients with STEMI and is an ACC/AHA class I recommendation.5-7 Although fibrinolysis has widespread availability and proven ability to improve coronary flow, limit infarct size, and improve survival in STEMI patients, many individuals with acute infarction are not suitable candidates. Patients with absolute contraindications to fibrinolytic therapy, certain relative contraindications, cardiogenic shock, and UA, and most NSTE MI cases, may not be eligible. The limitations of fibrinolytic therapy, as well as the benefits of percutaneous coronary intervention, suggest that rapidly performed PCI is often the treatment of choice in the STEMI patient. To provide the most significant benefit, PCI must be performed as soon as possible after the initial presentation. In certain other settings, PCI that is delayed is inferior to rapidly administered fibrinolytic agents, assuming that the patient has no contraindications to this therapy.

Fibrinolytic Therapy

Fibrinolytic Agent Selection. Options for fibrinolytic therapy include streptokinase (the original fibrinolytic agent) and three types of plasminogen activator: tissue-type plasminogen activator (t-PA) and two recombinant tissue-type plasminogen activators, r-PA (reteplase) and tenecteplase (TNK). Initial studies comparing streptokinase with slower administration of t-PA have shown no difference in outcomes in the setting of AMI. Subsequent studies, however, have shown improved outcomes with the use of t-PA compared to streptokinase in the setting of AMI, due to so-called accelerated administration of the former agent. Due to more effective options for fibrinolytic therapy, and easier to administer alternatives, streptokinase is no longer marketed in the United States. It is still used in many areas of the world due to its low cost when compared to the other fibrinolytic options.

Fibrinolytic practice remains highly affected by early studies testing the hypothesis that early and sustained infarct vessel patency is associated with better survival rates in patients with AMI. Investigators have studied multiple different fibrinolytic strategies and found that accelerated t-PA given over 90 minutes, plus IV heparin, shows improved results when compared to streptokinase in combination with multiple forms of anticoagulation. Unlike in previous trials, t-PA was given in a more aggressive, front-loaded, 90-minute infusion (referred to as accelerated t-PA). In addition to mortality, coronary artery patency and degree of normalization of flow were found to be directly affected by this accelerated t-PA administration. This was the first proven association of the relationship between early coronary artery patency and improved clinical outcome. The accelerated t-PA patients showed significant mortality benefit following treatment (15%), and the benefit out to 1-year follow-up was highly consistent across virtually all subgroups, including older patients, AMI location, and time since symptom onset. Also, the angiographic evaluation demonstrated a strong relationship between TIMI flow and outcome. Patients with strong forward flow (ie, TIMI grade 3 flow) at 90 minutes had significantly lower mortality rates than patients with little to no flow. The mechanism for this benefit was found to be earlier, more complete infarct vessel patency with accelerated t-PA; this early t-PA patency advantage over other agents was lost by 180 minutes after symptom onset. As would be expected, patients with the higher risk derived the most substantial benefit with accelerated t-PA compared with streptokinase in this large study. Accelerated t-PA is associated with increased risk of hemorrhagic strokes compared to streptokinase, but the combined endpoint of death and disabling stroke still favors the accelerated t-PA regimen.

Other large studies have compared accelerated t-PA with r-PA; r-PA can be administered in a fixed, double-bolus dose with no adjustment required for weight, which simplifies administration. r-PA has been found to be equivalent to accelerated t-PA, and results have been nearly identical for the two drugs. The one exception was the patient with presentation more than 4 hours after onset of symptoms, a significant number of patients in many institutions. In this group, accelerated t-PA may be superior to r-PA because of its greater fibrin specificity.

In the setting of STEMI, TNK has been found to have several potential benefits: (1) its longer half-life allows it to be administered as a single bolus; (2) it is 14 times more fibrin-specific than t-PA and even more so than r-PA; and (3) it is 80 times more resistant to plasminogen activator inhibitor type 1 than t-PA. In comparisons of single-bolus TNK (30–50 mg on the basis of body weight) or accelerated t-PA (100 mg total infusion) in the setting of AMI, there were no differences in mortality or intracranial hemorrhage. However, there may be benefit in 30-day mortality among patients with presentation more than 4 hours after onset of symptoms in those treated with TNK, as well as fewer nonintracranial major bleeding episodes in this group. On the basis of these results, it is concluded that TNK is equally or minimally more effective, particularly in late presenters. Concerning adverse reactions, TNK also appears modestly safer than accelerated t-PA. Finally, because of its single-bolus administration, TNK is
markedly easier to use in prehospital environments and the ED. At present, it appears that TNK is marginally more effective, minimally safer, and easier to administer than t-PA, and thus is recommended. Furthermore, cost differences are minimal and likely will not affect medical decision making in the ED.

**Eligibility Criteria for Fibrinolytic Agent Therapy.** In the absence of contraindications, fibrinolytic therapy should be considered in patients with STEMI and the onset of ischemic symptoms within the previous 12 hours when it has been anticipated that primary PCI cannot be performed within 120 minutes of first medical contact. The following section discusses the specific issues regarding fibrinolytic agent eligibility.

**12-Lead Electrocardiogram.** Combined with the patient’s history and physical examination, the 12-lead ECG is the key determinant of eligibility for fibrinolysis. The electrocardiographic findings should be consistent with STEMI based on the European Society of Cardiology (ESC)/American College of Cardiology Foundation (ACCF)/AHA/World Heart Federation Task Force for the Universal Definition of Myocardial Infarction. These findings include diagnostic ST elevation in the absence of LVH or LBBB, including ST elevation at the J point in at least two contiguous leads more than 2 mm in men or more than 1.5 mm in women in leads V₁ and V₃ and/or more than 1 mm in other contiguous chest or limb leads. Other electrocardiographic findings that should be considered for fibrinolytic therapy include the following: (1) ST elevation in aVR with coexistent multilead ST depression, concerning for proximal LAD or left main coronary artery occlusion; and (2) evidence of posterior transmural injury (posterior STEMI) indicated by ST segment depression in two or more precordial leads (V₄₋₅). Patients with new LBBB and AMI are at increased risk for a poor outcome and benefit significantly from the administration of rapid reperfusion therapy if they are experiencing an AMI. The new development of LBBB in the setting of AMI suggests proximal occlusion of the LAD artery, placing a significant portion of the left ventricle in ischemic jeopardy. However, new or presumably new LBBB at presentation should not be considered diagnostic of AMI in isolation. The finding of a new or presumably new LBBB at presentation of AMI occurs infrequently and, because of this poor diagnostic accuracy, an isolated new LBBB is no longer considered a STEMI equivalent. Rather, one of the more specific electrocardiographic findings to identify STEMI in the setting of LBBB, as defined by Sgarbossa, should be present before an LBBB is considered for STEMI treatment. A new or presumably new LBBB in a patient with a classic presentation of AMI who is very ill from an ACS perspective should be expeditiously evaluated with prompt cardiology consultation, if possible, to expedite cardia-focused care.

Patients with STEMI in anterior, inferior, or lateral anatomic locations benefit from fibrinolytic therapy. Acute, isolated posterior wall MI, diagnosed by posterior leads, may be another electrocardiographic indication for fibrinolysis. Although unresolved in large fibrinolytic agent trials, patients with isolated posterior AMI may be considered for reperfusion therapy; the emergency clinician at the bedside is in most appropriate position to make these treatment decisions.

Fibrinolytic therapy should not be used routinely in patients with only ST segment depression on the 12-lead ECG; in fact, the mortality rate may actually be increased. Multiple studies have demonstrated a significant increase in mortality in fibrinolytic-treated patients who presented only with ST segment depression. Acute posterior wall AMI presenting with anterior ST segment depression, as noted, can be considered an exception to this general statement.

**Patient Age.** Past trials do not provide evidence to support withholding fibrinolytic therapy or choosing one particular agent over another on the basis of the patient’s age. It is general consensus at this point that age alone should no longer be considered a contraindication to fibrinolytic therapy. It must be noted, however, that patients older than 75 years do have a higher incidence of hemorrhagic stroke than younger patients.

**Time From Symptom Onset.** The generally accepted therapeutic time window for administration of a fibrinolytic agent after the onset of STEMI is 12 hours. Patients treated within the first 6 hours of STEMI have the best outcome. Later administrations, from 6 to 12 hours after STEMI onset, also confer benefit, although of a lesser magnitude. The Late Assessment of Fibrinolytic Efficiency (LATE) trial, which compared fibrinolytic therapy with placebo, found a significant 26% decrease in 35-day mortality in patients treated with t-PA, heparin, and aspirin 6 to 12 hours after the onset of symptoms. There was no significant decrease in mortality among patients treated 12 to 24 hours after symptom onset.

**Blood Pressure Extremes.** Patients with a history of chronic hypertension should not be excluded from fibrinolytic therapy if their blood pressure is adequately controlled or can be lowered to acceptable levels with standard therapy for ischemic chest pain. The admission blood pressure is also an important indicator of risk of intracerebral hemorrhage. It has been shown that the risk of cerebral hemorrhage increases with systolic blood pressure higher than 150 mm Hg on admission and further increases when systolic blood pressure is 175 mm Hg or higher. Despite an increased mortality rate during the acute setting, fibrinolytic therapy in the setting of hypertension has shown an overall long-term benefit for patients with systolic blood pressure higher than 150 to 175 mm Hg. Although the literature appears to indicate an acceptable risk-benefit ratio for patients with substantially increased systolic blood pressure, a persistently elevated blood pressure—during the ED presentation—that is higher than 200/120 mm Hg is generally considered to be an absolute contraindication to fibrinolytic therapy.

The benefit of fibrinolytic therapy in patients with hypertension is unclear. Multiple trials have shown no apparent reduction in mortality rate with fibrinolytic therapy among patients classified as Killip class III or IV. However, reviews of data on STEMI patients have demonstrated that patients with an initial systolic blood pressure below 100 mm Hg who were not treated with fibrinolytic therapy had a very high risk of death (35.1%), and those who were treated with fibrinolytic therapy had the largest absolute benefit (60 lives saved/1000 patients). Although cardiogenic shock and CHF are not contraindications to fibrinolysis, PCI is the preferred method of reperfusion if it can be accomplished on site.

**Retinopathy.** Active diabetic hemorrhagic retinopathy is a strong relative contraindication to fibrinolytic therapy because of the potential for permanent blindness caused by intraocular bleeding. There is no reason, however, to withhold the use of a fibrinolytic agent in a diabetic patient with evidence of simple background retinopathy. Patients with diabetes mellitus who sustain a STEMI have an almost doubled incidence of mortality. It is impossible to determine the presence or absence of active retinal hemorrhage in the ED during the care of STEMI; thus, the emergency clinician should consider the risk-benefit analysis with respect to the presentation and involve the patient in the decision making.

**Cardiac Arrest Requiring Cardiopulmonary Resuscitation.** CPR is not a contraindication to fibrinolytic therapy unless CPR is prolonged—more than about 10 minutes—or extensive chest trauma from manual compression is evident. Although the in-hospital mortality rate is higher in AMI patients who experience cardiac arrest and then receive fibrinolytic agents in the ED, no difference has been found in the rates of bleeding complications. Specifically, hemothorax and cardiac tamponade were not diagnosed in cardiac arrest patients receiving CPR and
fibrinolytics who survived to admission. Even CPR prolonged beyond 10 minutes does not appear to be associated with higher rates of complication. Again, the emergency clinician should consider the risk-benefit analysis with respect to the presentation in this high-acuity, complex medical situation.

**Previous Stroke or Transient Ischemic Attack.** A history of a previous stroke or TIA is a major risk factor for hemorrhagic stroke after treatment with fibrinolytic therapy. A history of previous ischemic stroke should remain a strong relative contraindication to fibrinolytic therapy, and previous hemorrhagic stroke is an absolute contraindication.

**Previous Myocardial Infarction or Coronary Artery Bypass Graft.** In the setting of STEMI, a previous MI should not preclude consideration for treatment with fibrinolytic agents. Without treatment, there is a potential for greater loss of function in the newly infarcting region of the myocardium. In patients with a previous MI, studies of fibrinolysis have demonstrated a 26% relative mortality rate reduction, and patients with a history of past MI who received fibrinolytic therapy for recurrent acute infarction have a decreased mortality rate compared to control patients without fibrinolytic therapy.

Many studies have reported successful fibrinolysis in STEMI patients with a prior CABG, but these patients should be preferentially considered for direct angioplasty, if immediately available, or combined fibrinolysis and rescue angioplasty. Complete thrombotic occlusion of the bypass graft is the cause of AMI in approximately 75% of cases as opposed to native vessel occlusion. Because of the large mass of thrombus and absent flow in the graft, conventional fibrinolytic therapy may be inadequate to restore flow.

**Recent Surgery or Trauma.** Recent surgery or trauma is considered a relative contraindication to fibrinolytic therapy. The term recent has been subject to variable interpretation in fibrinolytic trials. The ACCF/AHA guidelines list significant head or facial trauma in the past 3 months and intracranial or intraspinal surgery within the past 2 months as absolute contraindications to fibrinolytic therapy in STEMI. Major surgery within the past 3 weeks and recent internal bleeding (2–4 weeks) are also listed as relative contraindications to fibrinolytic therapy in the setting of STEMI.

**Menstruation.** Because natural estrogen is partially cardioprotective, there is very little clinical experience with fibrinolysis in premenopausal women. Gynecologists have indicated that any excessive vaginal bleeding that may occur after undergoing fibrinolytic therapy should be readily controllable by vaginal packing and therefore can be considered as a compressible site of bleeding.

**Percutaneous Coronary Intervention.** Although fibrinolysis has widespread availability and a proven ability to improve coronary flow, limit infarct size, and improve survival in STEMI patients, many individuals with acute infarction are not suitable candidates. PCI has many theoretic advantages over fibrinolysis, including an increased number of eligible patients, lower risk of intracranial bleeding, significantly higher initial reperfusion rate, earlier definition of coronary anatomy with rapid triage to surgical intervention, and risk stratification allowing safe, early hospital discharge. Potential disadvantages include lack of operator expertise and numerous catheterization laboratory logistic issues, including limited geographic availability and delays to therapy application. However, it must be stated that PCI is superior when applied early and rapidly in the STEMI patient, yet it loses its treatment advantage over fibrinolysis if time to procedure is prolonged.

Several trials of varying sizes comparing primary PCI with fibrinolysis have been reported. Interventions in the early trials were performed before the widespread adoption of coronary stents with GPI. Despite a clear and consistent benefit of PCI in restoring patency of the infarct-related artery, differences in mortality in the individual trials were difficult to evaluate because of the smaller sample sizes. It has been shown that compared with standard-dose t-PA, PCI reduces the combined occurrence of nonfatal reinfarction or death, is associated with a lower rate of intracranial hemorrhage, and results in similar left ventricular function. Other studies have indicated that primary angioplasty is associated with a higher rate of patency of the infarct-related artery, less severe residual stenotic lesion, better left ventricular function, and less recurrent myocardial ischemia and infarction than in patients receiving streptokinase.

Multiple studies comparing PCI versus t-PA have now shown a decrease in death, reinfarction, and nonfatal disabling stroke in patients with STEMI when treated with PCI. These results even held true in the setting of accelerated t-PA administration and patients requiring transfer for PCI when the transfer can occur within 3 hours. Multiple studies continue to support the findings that PCI is superior to fibrinolytic therapy in the setting of STEMI, even where rapid transfer for PCI is necessary.

The combination of dual-antiplatelet therapy in addition to PCI with stenting has been shown to reduce the risk of death, recurrent MI, stroke, or need for urgent revascularization by about 50% compared to PCI with angioplasty alone. This dramatic reduction in death and cardiovascular events has led to PCI with stenting to replace simple angioplasty as the treatment of choice for STEMI.

The longer term results with PCI, however, are less well established. Much of the earlier literature comparing acute reperfusion therapies in STEMI did not include the use of coronary stenting during PCI or contemporary dual-platelet therapy. Previous large studies showed no overall mortality advantage of PCI at 6 months. The issue of long-term outcome in PCI-managed STEMI patients is further complicated by drug-eluting stents (DESs). Early studies used bare metal stents, which, in the setting of an acute thrombotic event such as STEMI, raised concern regarding stent thrombosis with obstruction and recurrent AMI. PCI with stenting is superior to standard angioplasty. The addition of DESs to the equation has produced less favorable results, however, with similar rates of MI and death coupled with a lower rate of revascularization in the DES patients at several years postintervention.

**Rescue Percutaneous Coronary Intervention.** Historically, rescue PCI was considered advantageous in patients whose infarct-related arteries failed to reperfuse after fibrinolytic therapy. These patients are profoundly ill, with a markedly worse outcome. Some centers routinely catheterize patients after fibrinolytic therapy to determine whether successful reperfusion has occurred and to perform PCI if feasible. Other centers catheterize patients after fibrinolytic therapy only if there is clinical evidence that the infarct-related artery fails to open, as suggested by continued chest pain or persistent ST segment elevation.

Large trials have compared outcomes after rescue PCI with a conservative management strategy in STEMI patients in whom fibrinolysis has failed. Rescue PCI has not been associated with improved short-term or long-term survival; furthermore, increased rates of stroke and transfusion were noted in this group. In a meta-analysis of STEMI patients who did not achieve satisfactory reperfusion after fibrinolysis, rescue PCI was not associated with mortality reductions. In this very ill group, however, the incidence of heart failure and recurrent infarction was reduced. Repeat fibrinolysis was not associated with significant improvements in mortality or recurrent infarction. Although the decision to offer rescue PCI to the patient in whom fibrinolytic therapy has failed remains controversial, evidence favors rescue PCI (class IIa recommendation) and does not support the use of repeat fibrinolysis.

**Facilitated Percutaneous Coronary Intervention.** Facilitated percutaneous coronary intervention refers to combination
therapy involving fibrinolysis coupled with emergent PCI. This concept originally was developed to maximize therapy in STEMI patients who would be transferred urgently for PCI. The patient would receive the additive benefit of medical therapy (a fibrinolytic agent) before transfer, optimizing perfusion in the culprit artery before arrival at the PCI-capable institution. Unfortunately, outcomes from this facilitated approach are less optimal than fibrinolysis or standard PCI alone. In light of these results, the continued use of a facilitated PCI approach should not be used at this time outside of a scientific investigation.

Choice of Reperfusion Therapy. As noted, the two primary choices for reperfusion therapy in the STEMI patient include fibrinolysis and PCI. Important issues to consider in this treatment choice include the selected form of reperfusion therapy, total elapsed time of infarction, patient's candidacy for fibrinolysis (ie, presence or absence of contraindications), type of hospital facility (ie, PCI-capable), and anticipated time to transfer to the PCI-capable facility. Regardless of the strategy selected, the system’s reperfusion goal should be a first medical contact to therapy that is within 120 minutes—a 30-minute goal for the initiation of fibrinolysis and 120-minute goal for PCI performance. These time periods include transfer for PCI; in other words, if a transfer from one hospital to another is part of an individual patient’s care plan, the first medical contact is the initial hospital. 5–7

With respect to treatment benefit, there are important time-based differences when one considers PCI and fibrinolysis. First, PCI is the preferred strategy for STEMI reperfusion therapy, assuming that it can be performed in timely fashion. Second, the changing impact on mortality, as total infarction time increases, is much more pronounced with fibrinolysis as compared to PCI. The success of PCI in reestablishing perfusion in the early hours after STEMI does not change significantly with time; conversely, the ability of fibrinolytic therapy to restore coronary perfusion decreases significantly with increasing time of infarction, reaching a significant reduction at approximately 6 hours of total STEMI time.

The following discussion considers the preferred reperfusion strategy for the STEMI patient arriving at non–PCI-capable hospital. The patient should be considered for immediate transfer without fibrinolysis to a PCI-capable facility within an appropriate time period (AHA class I recommendation). 5–7 If the patient is a candidate for fibrinolysis and cannot be transferred to a PCI-capable hospital within an appropriate time period, immediate fibrinolytic therapy should be administered, with consideration of subsequent transfer for cardiac catheterization within the next 24 hours; at this time, PCI can be performed, if indicated. If the patient is not a fibrinolytic candidate, transfer should be arranged as soon as possible. 5–7 In this series of recommendations, “appropriate time period” is a key phrase and must be considered from the perspective of two important variables—the total time duration of acute infarction at the time of presentation and anticipated time to performance of PCI.

From these two perspectives, the following general statements regarding reperfusion management of the STEMI patient who arrives at a non–PCI-capable hospital can be made:

- If presentation is within 2 hours or less of symptom onset, consider immediate fibrinolysis unless transfer time for PCI is anticipated to be no more than 60 minutes (AHA class IIB recommendation).
- If presentation is within 2 to 3 hours of symptom onset, consider immediate fibrinolysis or PCI if time to transfer time for PCI is anticipated to be no more than 60 to 120 minutes (AHA class IIB recommendation).
- If presentation is within 3 to 12 hours of symptom onset, consider PCI as opposed to initial fibrinolysis if time to transfer for PCI is anticipated to be no more than 120 minutes (AHA class IIB recommendation).

As the total STEMI time increases, the overall effectiveness of fibrinolysis decreases significantly; at 6 hours of STEMI time, a longer delay allowing for transfer for PCI is a reasonable management option.

If the STEMI patient arrives at a PCI-capable hospital, PCI remains the reperfusion therapy of choice, with the same time constraints as noted above. The STEMI patient should arrive in the catheterization laboratory with initiation of procedure within 120 minutes of initial medical contact. 5–7 If PCI is not possible at the PCI-capable hospital and the patient is a fibrinolytic candidate, fibrinolytic therapy should be administered if a delay beyond 120 minutes is anticipated. Other candidates for PCI include high-risk STEMI patients, so-called late presenters (ie, >3 hours since the onset of STEMI symptoms), patients in cardiogenic shock, and individuals with contraindication to fibrinolysis. Furthermore, when the diagnosis of STEMI is in doubt, PCI is the most appropriate diagnostic and therapeutic strategy.

Hospitals should have a fibrinolytic therapy plan in place for the treatment of STEMI patients in the event of PCI delay or unavailability. If the time required to mobilize staff and arrange for PCI is prolonged, or if delays in transfer are anticipated, fibrinolysis is preferred within the first several hours of STEMI occurrence. Prior agreement between the ED and cardiovascular physicians at institutions with invasive capability must be obtained and a transfer pathway should be in place so that PCI consideration does not introduce further delays in fibrinolytic drug administration. Consensus clinical pathways limit additional delays in the administration of fibrinolytic agents for patients who are considered for PCI in STEMI.

It has been well established that delays to reperfusion therapy have negative consequences. Delays in reperfusion are associated with increased mortality for PCI and fibrinolysis treatment strategies and appear to be more pronounced in patients undergoing fibrinolysis.

A cooperative effort among all providers and units can markedly reduce the door to therapy time in STEMI patients. 5–7 A so-called STEMI alert system, analogous to the trauma alert approach, mobilizes hospital-based resources, optimizing the approach to the AMI patient. This system, whether activated by data gathered in the ED or in the field, has the potential to offer time-sensitive therapies in a rapid fashion. Emergency clinician activation of the catheterization laboratory has demonstrated very high rates of accurate STEMI diagnosis while markedly reducing the time to definitive therapy, with very low rates of inappropriate activation (ie, the STEMI mimicker). The ACC and AHA recognize the numerous challenges and potential difficulties in achieving these reperfusion therapy time goals.

Reperfusion Therapy in Cardiogenic Shock. Patients with STEMI experiencing cardiogenic shock, which occurs in up to 10% of cases, demand special consideration because of a mortality rate approaching 80%. Fibrinolysis is not effective in these patients, likely owing to a significantly lower coronary perfusion pressure. In circulatory shock states, the occlusive thrombus is not exposed to the fibrinolytic agent, resulting in clinical failure of the drug. In large fibrinolytic trials, STEMI patients in cardiogenic shock were not found to benefit from fibrinolysis. Conversely, primary PCI has been investigated in more than 600 patients in several small studies. A cumulative analysis has revealed a significantly lower mortality rate (45%) compared with placebo or historical controls.

In previous studies that compared the outcomes of STEMI patients in cardiogenic shock, patients were randomly assigned to emergency revascularization (PCI or emergent CABG) or initial medical stabilization, including fibrinolysis. Overall mortality at
30 days did not differ significantly between the revascularization and medical therapy groups, but the 6-month mortality was lower in the revascularization group. This finding—of reduced mortality in PCI compared to fibrinolytic therapy for patients with cardiogenic shock in the setting of STEMI—has been repeated in multiple studies. Thus, emergency revascularization with PCI or CABG is preferred for patients with STEMI complicated by cardiogenic shock, irrespective of the delay to treatment. Fibrinolytic therapy should be considered in eligible patients who are otherwise unsuitable candidates for PCI or CABG.\(^6\)

**Resuscitated Cardiac Arrest With Suspected Acute Coronary Syndrome**

In the patient who has been resuscitated from out-of-hospital cardiac arrest (OHCA), postresuscitation care in the ED includes many important areas of management. Beyond the basic critical care interventions, urgent coronary reperfusion should be considered in the resuscitated OHCA patient who has experienced a cardiogenic cardiac arrest. More than 50\% of these resuscitated, cardiogenic, OHCA patients who have undergone urgent coronary reperfusion survive to hospital discharge, a survival rate higher than the approximate 10\% survival rate of all patients experiencing OHCA cardiac arrest in the out-of-hospital arena. Most of these patients have satisfactory neurologic function at the time of hospital discharge.\(^5\) The literature base considering this issue is heterogeneous, addressing a broad range of resuscitated patient types, including important differences in the various initial cardiac arrest rhythms, range of subsequent mental status after the return of spontaneous circulation (ROSC), and cardiopulmonary status in the ED. Thus, the most appropriate candidate types for urgent coronary reperfusion have not been conclusively identified.\(^5,10-53\)

Most OHCA patients have a cardiogenic cause responsible for the cardiac arrest. ACS is considered to be the most frequent cause, including STEMI and NSTEMI; not surprisingly, the ECG demonstrates ST segment deviation in many of these patients. For example, the alert patient with ventricular tachycardia or ventricular fibrillation who has been resuscitated and demonstrates STEMI on the ECG likely will benefit significantly from emergent PCI.\(^7\) Although STEMI patients are the most likely group to achieve benefit from emergent cardiac catheterization with PCI, if indicated, electrocardiographic findings should not be considered as strict selection criteria for performing urgent PCI. It has been noted that patients with electrocardiographic presentations other than STEMI derive benefit from this intervention.\(^6,51,52\) Importantly, a clinical presentation of coma after cardiac arrest should not be considered a contraindication to reperfusion therapy because this finding is commonly present. Multiple investigations have followed patients with resuscitated cardiac arrest complicated by STEMI. Among those patients who were conscious at the time of PCI, invasive therapy restored coronary perfusion in more than 90\% of cases, and all these patients survived without neurologic deficit. The outcome in the comatose patient subgroup was less favorable, with approximately a 50\% survival rate and good neurologic outcome, yet still markedly better than the average OHCA victim who has achieved ROSC.\(^1\)

Therapeutic hypothermia used in the resuscitated, unresponsive OHCA patient with presumed cardiogenic cause and, when combined with PCI, demonstrates an impressive rate of survival, with good neurologic outcome. Based on previous case series therapeutic hypothermia coupled with PCI demonstrates a significantly improved rate of survival.

The AHA, in their 2015 guidelines, have suggested that urgent cardiac catheterization with PCI, if indicated, should be considered in the resuscitated OHCA patient, regardless of the presence or absence of ST segment elevation.\(^7\) These guidelines noted that “…coronary angiography with PCI, if indicated, should be performed emergently in those resuscitated patients with suspected cardiogenic cardiac arrest who demonstrate electrocardiographic ST segment elevation…”\(^7\); this recommendation is a class I indication. Furthermore, addressing two specific presentation types, emergent coronary angiography “…is a reasonable intervention in the resuscitated cardiogenic cardiac arrest …[in patients who are comatose and do not demonstrate ST segment elevation on the ECG]”\(^7\) (class IIA indication). It is reasonable to consider including PCI as part of a standard postresuscitation care program because almost 50\% of cardiogenic cardiac arrest survivors have an acute occlusion or culprit lesion amenable to intervention.\(^50\) For a range of issues, PCI is the preferred reperfusion strategy in the post-ROSC patient; in this patient presentation with STEMI, in which PCI is not available in timely fashion, fibrinolysis can be considered, assuming that there are no contraindications.

Cardiac catheterization with the possibility of PCI, if warranted, can offer survival and functional benefits to selected patients. Patient selection for emergent PCI after resuscitation from OHCA, however, is a challenging, difficult to answer question. What is clear in this situation is that a subset of these patients, with and without ST segment elevation, alert or comatose, do benefit significantly from emergent reperfusion therapy, delivered along with other appropriate postresuscitation management. With the significant benefit derived by some individuals, emergent reperfusion should be considered in the OHCA patient who has achieved ROSC. In this consideration, the most appropriate discussion should include the emergency clinician and cardiologist. It must be noted that the emergency clinician can suggest and advocate for such and intervention but the invasive cardiologist ultimately makes this decision, as is appropriate in the turnover of care that is occurring.

**Management Summary: Potential Pharmacologic Management Approach**

The patient with stable or resolved chest pain, with a normal to minimally abnormal ECG and a negative serum marker, is best managed initially with NTG sublingually or topically in combination with aspirin. Resolution of the discomfort with continued stability probably does not warrant further ED pharmacologic management. Continued or recurrent pain in the ED may be treated with parenteral morphine sulfate. Continued pain may ultimately require IV NTG, heparinization with UFH or LMWH, and additional antiplatelet therapy with a thienopyridine (eg, clopidogrel, ticagrelor). The patient with stable UA (ie, new-onset or altered pattern but now symptom-free and lacking abnormal serum markers and an abnormal ECG) does not require heparin or other more aggressive platelet inhibition therapy in most cases.

The ACS patient with an abnormal ECG, particularly ST segment and T wave abnormalities, or elevated serum marker levels may warrant numerous therapies, including ASA, heparin, and other antiplatelet agents (typically a thienopyridine). NTG may be administered by the topical or IV route. The patient with recurrent angina may also benefit from such an approach. Heparin therapy is generally indicated in this case.

The AMI patient without ST segment elevation—the NSTEMI patient—requires aspirin, NTG, heparin, a thienopyridine, or an alternative second antiplatelet agent, and morphine sulfate. The patient with STEMI is treated with the preceding medications noted and should be considered for urgent revascularization, achieved by fibrinolytic agents, PCI, or, in the rare case, CABG.

**DISPOSITION**

Just as coronary artery disease and ACS represent a spectrum of disease, there is a similar spectrum of disposition options for
patients presenting to the ED with chest pain or other complaints concerning for ACS. These options include rapid transport to the cardiac CCL within minutes of arrival for emergent intervention, ICU admission, acute care admission with cardiac monitoring, observation unit admission (actual or virtual), and discharge to home after evaluation. Patients with evidence of an acute or ongoing ACS event will require admission to the hospital. The final location of these admissions will depend on the patient’s clinical presentation, electrocardiographic findings, results of the troponin assay, and cardiorespiratory status.

If the patient’s presentation and ECG are consistent with STEMI, the disposition is determined by the reperfusion options available at the facility. In a facility where interventional cardiology and PCI are available, the patient can be urgently transported to the CCL for reperfusion via PCI, as long as this can be accomplished without delay. If PCI is not available as a timely option, fibrinolytic therapy should be initiated rapidly. Regardless of the reperfusion strategy of choice, patients with STEMI will require ICU admission due to the significant risk of adverse events during the first 24 hours of hospitalization. All hospitals, regardless of their size or resources, should have a clear care pathway for STEMI patients that may include CCL activation or fibrinolysis, followed by admission to the ICU; an expedited transfer should also be considered for the appropriate patient, dependent on the initial facility’s capabilities.

In patients who have evidence of ACS without STEMI, their disposition is based on the emergency clinician’s risk assessment of the patient and his or her clinical presentation. Patients with high-risk presentations, including dynamic electrocardiographic changes, uncontrolled ischemic pain, or rising troponin levels (consistent with NSTEMI or unstable angina) will likely benefit from ICU-level care and monitoring due to their significant risk of adverse events.

If the patient has no evidence of active ischemia, most risk stratification tools recommend separating patients into categories based on the risk of ACS and adverse events. High-risk patients without dynamic electrocardiographic changes or elevated troponin levels often benefit from hospitalization in a monitored bed, with further diagnostic testing and management. Intermediate-risk patients often benefit from abbreviated stays in an observation unit (structural or virtual unit) for repeat troponin level tests and possible provocative testing or anatomic imaging, if indicated. Patients at low risk of ACS can often receive evaluation in the ED setting, followed by discharge with primary care follow-up and possible outpatient testing, as indicated.

Transfer of a Patient With Acute Coronary Syndrome

There are several indications for the transfer of a patient with ACS to a facility with PCI capability. These include rapid access to PCI, persistent hemodynamic instability or ventricular dysrythmias, and postinfarction or postreperfusion ischemia. Hospital transfer for PCI is also suggested for patients with fibrinolytic contraindications who may benefit from PCI or CAGB.

The urgent transfer of a fibrinolytic-eligible STEMI patient to another institution for PCI is not recommended until fibrinolytic therapy has been initiated if a delay in PCI application is anticipated. The ACC/AHA guidelines have noted that in hospitals without PCI capability, immediate transfer for primary PCI is a treatment option when it can be accomplished within 60 to 120 minutes of first medical contact, depending on the duration of STEMI at the time of presentation. If delays in PCI performance are anticipated, and the patient is an acceptable candidate for fibrinolysis, the fibrinolytic should be started before or during transport to the receiving hospital. This decision is made in conjunction with the receiving cardiologist.

Many institutions are not PCI-capable. Thus, the decision for the emergency clinician involves not only the relatively simple fibrinolysis versus PCI issue but also the potential need for urgent transfer to a larger center. Previous studies have explored the potential benefit of PCI over fibrinolysis and the all-important impact of transfer of the STEMI patient in a noninterventional hospital. These studies revealed about a 25% reduction in the composite endpoints of death, recurrent infarction, stroke, and/or revascularization in fibrinolytic patients compared to those in the PCI group. The conclusion was that the early benefit from a transfer-related invasive strategy was sustained over long-term follow-up, but the benefit was largely a result of a lower event rate in the PCI patients in the first 30 days after presentation.

The potential need to transfer the STEMI patient over long distances can also affect reperfusion therapy decisions. This is usually seen in rural areas with long transport times to the nearest PCI facility. In this setting, organized processes for rapid transfer should be in place to address the expected delays, including a rapid initiation of transfer by the emergency clinician, an agreed-on expedited transfer process to the PCI center, and rapid access to a transport vehicle (ground or air) that will be needed for safe transport. Multiple investigations have suggested that rapid transfer for PCI in the STEMI patient can occur in the rural setting with acceptable time to therapy.

KEY CONCEPTS

- Angina-equivalent symptoms that are not characteristically associated with ACS vary widely and often distract from the diagnosis. The patient’s age, diabetes status, ethnicity, and gender are considered with an atypical history.
- Limitations of the 12-lead ECG in ACS include initial nondiagnostic findings, evolving fluctuations with ongoing symptoms, anatomic myocardial blind spots, and confounding or obscuring patterns, such as LBBB.
- Patients with proximal left anterior descending artery stenosis (Wellens syndrome) may have deeply inverted or biphasic T waves in the anterior precordial leads.
- ST segment elevation in lead aVR more than 0.5 mV suggests left main coronary artery disease.
- Functional testing strategies for ACS include graded exercise testing, echocardiography, and myocardial scintigraphy. Graded exercise testing, with or without nuclear scintigraphy, can be used in the patient with low to moderate likelihood of CAD who is able to exercise. Myocardial scintigraphy with pharmacologic stress can be used in the debilitated or older patient (ie, unable to exercise).
- Echocardiography with pharmacologic stress is appropriate for the woman older than 45 years, the patient with diabetes mellitus, and the patient with other forms of organic heart disease (eg, valvular dysfunction, low cardiac output states).
- The use of coronary CT angiography is most appropriate in the younger patient; excessive coronary calcification can reduce the ability of CCTA to evaluate the patient for significant CAD reliably.
- Fibrinolysis is not effective in patients with STEMI who are in cardiogenic shock.
- Unless used for rate control of supraventricular dysrhythmia in a patient who cannot tolerate beta blockade, calcium channel blockade is not recommended for those with ACS.

CHAPTER 68: QUESTIONS & ANSWERS

68.1. A 40-year-old man presents with a 3-hour history of left-sided chest pain, slightly worse in the supine position, associated with mild dyspnea and diaphoresis. He is 2 weeks status post–left anterior/lateral subendocardial myocardial infarction (MI), with acute stenting of the left anterior descending and circumflex arteries. He is unable to discern if this pain is the same as his original cardiac pain. His current medications are aspirin, 81 mg/day, lovastatin, 80 mg/day, amlodipine 10 mg/day, and clopidogrel 75 mg/day. His electrocardiogram (ECG) is shown here. Cardiac troponin I is within normal limits. Vital signs are temperature, 38°C oral, heart rate (HR), 110 beats/min, blood pressure (BP), 153/96 mm Hg, respiratory rate (RR), 22 breaths/min, and O₂ saturation, 96%. What is the most likely diagnosis?

A. Coronary ischemia
B. Dressler’s syndrome
C. Infarct pericarditis
D. Pleuritic chest wall pain
E. Ventricular aneurysm formation

Answer: B. Dressler’s syndrome is a late sequela of typically nontransmural MI. It may occur 1 week to several months post MI. It is an immune-mediated process sometimes associated with pleural or pericardial effusion. Infarct pericarditis is usually seen within the first week after a transmural infarct, and the classic pericarditis electrocardiographic finding may be overshadowed by the MI changes. PR segment depression is seen in both entities. The characteristic ECG, presence of fever, and pain with recumbency argue for this diagnosis. A ventricular aneurysm would be expected after transmural MI; the ECG will demonstrate ST segment elevation, usually with prominent Q waves and T waves of diminished amplitude. Myocardial ischemia is a possibility, but troponin is negative and ECG is noncontributory.

68.2. A 37-year-old male renal dialysis patient presents with a 6-hour history of intermittent left-sided chest pain. He missed his last dialysis session due to feeling ill. His past history is significant for hypertension with secondary renal failure, tobacco use, and hypercholesterolemia. His current medications are amlodipine, 10 mg/day, a statin, and his renal failure medications. Vital signs are temperature, 36.7°C oral, HR, 92 beats/min, BP, 170/110 mm Hg, respiratory rate (RR), 22 breaths/min, and O₂ saturation, 95%. His ECG is shown below. The serum potassium level is 5.8 mEq/L. What is the most important intervention?
A. Calcium gluconate, 1 g IV, followed by dextrose, 100 g, and regular insulin, 10 units IV
B. Emergent dialysis
C. IV enoxaparin
D. IV metoprolol
E. Nitroglycerin, aspirin, 325 mg orally, and cardiology consultation

Answer: E. The ECG shows asymmetric hyperacute T waves, possibly consistent with coronary ischemia. This is clinically the early electrocardiographic manifestation of AMI. The differential diagnosis of hyperacute T waves is ischemia, hyperkalemia, benign early repolarization, left ventricular hypertrophy, left bundle branch block, and pericarditis. The asymmetry of the T waves argues for ischemia, as does the relatively modest rise in the serum potassium. Enoxaparin might be indicated, but only as part of an acute coronary regimen with appropriate renal dosing. Beta blockers would worsen his hyperkalemia and would have to be carefully considered before administration.

68.3. A 63-year-old woman with a past medical history of diabetes presents with altered mental status, diaphoresis, and substernal chest pain for 4 hours. Vital signs are HR, 96 beats/min, BP, 80/50 mm Hg, RR, 26 breaths/min, temperature, 37°C, and O2 saturation, 94%. The ECG clearly demonstrates a large, anterior ST segment elevation MI. Your institution does not have a cardiac catheterization laboratory. The closest hospital with a cardiac catheterization laboratory is 2 hours by ground, and no aircraft is available due to weather. After normal saline boluses, what is the most appropriate treatment?
A. Administer aspirin, PSY12 inhibitor, intravenous (IV) unfractionated heparin (UFH), vasopressor therapy as needed, and admit to your institution.
B. Administer aspirin, PSY12 inhibitor, IV UFH, and immediate transfer to primary percutaneous coronary intervention (PCI) center by ground emergency medical services (EMS).
C. Administer aspirin, PSY12 inhibitor, IV UFH, IV fibrinolysis, and immediate transfer to the PCI center.
D. Administer aspirin, PSY12 inhibitor, IV UFH, and transfer to the primary PCI center when helicopter becomes available in 4 hours.

Answer: B. Patients who present with ST segment elevation myocardial infarction (STEMI) and cardiogenic shock should be preferentially treated with percutaneous coronary intervention (PCI) if there are no contraindications to mechanical reperfusion. Because PCI is the preferred therapy, a delay of beyond the usual threshold of 60 to 120 minutes from first medical contact to PCI for the administration of fibrinolitics is tolerated. Although a delay beyond 120 minutes is tolerable, it should be as small as possible.

68.4. A 48-year-old man with history of hypertension and hypercholesteremia presents with chest pain and hyperacute T waves in an anterior distribution on the initial ECG. During your initial history and physical examination, the patient experiences ventricular fibrillation that responds to cardiopulmonary resuscitation (CPR) and defibrillation after being pulseless for a period of 3 minutes. Following cardiac arrest, the patient is comatose, with the following vital signs: HR, 110 beats/min, BP, 160/98 mm Hg, RR, 12 breaths/min (intubated), temperature, 36.5°C, and O2 saturation, 96%. A repeat ECG demonstrates a large, evolving anterior STEMI.

Which of the following treatment plans is most appropriate?
A. Administer aspirin, PSY12 inhibitor, IV UFH, IV fibrinolysis, and admission to intensive care unit (ICU)
B. Administer aspirin, PSY12 inhibitor, IV UFH, IV fibrinolysis, initiation of therapeutic hypothermia, and admission to ICU
C. Neurologic examination for brain death and admission to palliative care because outcome almost universally fatal
D. Rapid revascularization with percutaneous coronary intervention (PCI), initiation of therapeutic hypothermia, and admission to ICU for comprehensive postresuscitation care
E. Supportive care, and admission to ICU

Answer: D. A neurologic examination immediately following cardiac arrest is poorly diagnostic of a favorable neurologic outcome with modern postresuscitation care. The sharp increase in survival with a favorable neurologic outcome has elevated rapid revascularization with percutaneous coronary intervention (PCI) and immediate application of therapeutic hypothermia as part of comprehensive postresuscitation care as a class I ACC/AHA recommendation. Although not contraindicated, fibrinolysis is inferior to PCI following cardiac arrest and should only be used when a patient is not a candidate for PCI.

68.5. Which of the following is an absolute contraindication to fibrinolytic therapy?
A. Age older than 75 years
B. Appendectomy performed 2 months ago
C. Previous coronary artery bypass grafting (CABG)
D. Previous hemorrhagic stroke
E. Systolic blood pressure of 175/90 mm Hg following administration of vasoactive agents

Answer: D. Although patients older than 75 years have a higher risk of intracerebral hemorrhage, age should not be considered a contraindication to fibrinolysis. Although prior CABG patients should be preferentially considered for PCI, there is no contraindication to fibrinolytic use in these patients if PCI is not available. Systolic blood pressure above 150 mm Hg is a risk factor for intracerebral hemorrhage. Only hypertension persistently above 200/120 mm Hg, despite reasonable efforts, should be considered an absolute contraindication. Recent major surgery or trauma is a relative contraindication for fibrinolysis; however, the term recent is variably defined in the fibrinolytic literature and never as more than 6 weeks.

68.6. Which of the following drugs provides mortality benefit in the setting of AMI?
A. Aspirin
B. Intravenous beta blocker
C. Intravenous morphine
D. Nitroglycerin
E. Oxygen

Answer: A. The ISIS-2 trial has demonstrated that aspirin independently reduces mortality by 23% in the setting of AMI. Intravenous morphine has not been shown to improve mortality and has been associated with mortality. Although nitroglycerin does improve symptoms and cause vasodilation, it has never been proven to improve mortality. Oxygen beyond that needed to maintain an oxygen saturation of 94% has been associated with additional mortality. The use of intravenous beta blockers does not offer significant benefit and is associated with an increased rate of adverse events.
68.7. A 42-year-old male patient presents with 45 minutes of chest pain. The ECG is depicted below. You are working at a noninvasive (ie, no PCI capability) hospital; transfer time to the closest major medical center with PCI capability is 4.5 hours considering weather and logistics. The patient has no contraindications for fibrinolysis. Which of the following statements is most appropriate?

A. The patient must be transferred rapidly to the closest PCI center, with initiation of appropriate β-adrenergic blocking agents and antiplatelet and anticoagulant therapies before transfer.

B. The patient should receive a fibrinolytic agent followed by appropriate antiplatelet and anticoagulant therapies with admission to your hospital’s ICU.

C. The patient should receive a fibrinolytic agent followed by appropriate antiplatelet and anticoagulant therapies, with transfer to the closest PCI center for immediate PCI.

D. The patient should receive a fibrinolytic agent followed by appropriate antiplatelet and anticoagulant therapies, with transfer to the closest PCI center within 24 hours for reevaluation and consideration of immediate PCI.

Answer: D. The ECG demonstrates an extensive anterolateral STEMI. The patient is young and has presented early in the STEMI evolution. This patient is at extreme risk due to the extensive nature of the STEMI and yet can benefit significantly from early reperfusion therapies. A delay of more than 60 to 120 minutes in this patient is not appropriate for the initiation of reperfusion therapies; furthermore, he is a candidate for a fibrinolytic agent. The early initiation of reperfusion therapy (fibrinolysis or PCI) is vital to reduce morbidity and mortality. Such a significant delay in this case for PCI is not justified, so a fibrinolytic agent is preferred. On arrival at the closest PCI center, the patient can be evaluated for PCI if he has not demonstrated successful reperfusion with resolution of chest discomfort and normalization of the ST segment elevation.
**CHAPTER 69**

**Dysrhythmias**

Donald M. Yealy | Joshua M. Kosowsky

---

**PRINCIPLES**

The term *dysrhythmia* denotes any abnormality in cardiac rhythm. In this chapter we review the electrophysiology of normal and abnormal cardiac impulse formation and conduction and then provide a general approach to dysrhythmia recognition and management, along with an overview of antidysrhythmic agents. Finally, we discuss the evaluation and treatment of specific dysrhythmias in the prehospital and emergency department (ED) settings.

**Cardiac Cellular Electrophysiology**

The electrophysiologic function of cardiac cells depend on an intact resting membrane potential. Membrane potential is largely the result of differential concentrations of Na$^+$ and K$^+$ on either side of the cell membrane, measuring approximately −90 mV in normal resting nonpacemaker cells. This gradient exists because of the Na$^+$–K$^+$ exchange pump and concentration-dependent flow of K$^+$ out of the cell. The influx of Ca$^{2+}$ through passive exchange with Na$^{+}$ also allows for conduction and myocardial contraction (Fig. 69.1).

In normal nonpacemaker cells, an electrical stimulus causes the membrane potential to become less negative, termed depolarization. When the membrane potential reaches −70 mV, specialized Na$^{+}$ channels open, causing a rapid influx of positive charge into the cell. This so-called fast channel activity further decreases the membrane potential and is augmented at 30 to 40 mV by a second slow channel that allows Ca$^{2+}$ influx. When these channels close, resting potential is restored by the sodium-potassium pump, an event termed repolarization (Fig. 69.2).

In nonpacemaker cells, depolarization from a second electrical stimulus is not possible when the membrane potential remains more positive than −60 mV, called the effective refractory period (Fig. 69.3). When the membrane potential reaches −60 to −70 mV, some fast channels are capable of responding but impulse propagation is not normal; this is known as the relative refractory period. At a membrane potential of −70 mV or less, fast channels are ready for activity (see Fig. 69.3).

Pacemaker cells differ from non–impulse-generating cells in that they can spontaneously depolarize via slow Na$^{+}$ influx. Dominant pacemaker cells are present in the sinoatrial (SA) node, but other pacemaker cells exist in the atrioventricular (AV) node, within the His-Purkinje system, and elsewhere. With a failure of normal pacemaking cells, or other pathologic conditions such as metabolic derangement or myocardial ischemia, nonpacemaker cells undergo spontaneous depolarization.

**Anatomy and Conduction**

The SA node is an area of specialized impulse-generating tissue at the junction of the right atrium and the superior vena cava. Its blood supply is from the right coronary artery (RCA) in 55% of patients and left circumflex artery (LCA) in 45%. The normal SA node produces spontaneous depolarization at a faster rate than other pacemakers and is usually the dominant pacemaker. In healthy adults, the SA node normally maintains a rate of 60 to 90 beats/min. Hypothermia and vagal stimulation slow the sinus rate, whereas hyperthermia and sympathetic stimulation increase the rate. Low or absent parasympathetic tone—for example, with certain drugs or after heart transplantation—creates a faster sinus rate.

In the absence of normal SA node impulses, other myocardial tissues may assume the role of pacemaker. The AV node has an intrinsic impulse-generating rate of 45 to 60 beats/min. Infranodal pacemakers within the His bundle, Purkinje system, and bundle branches maintain intrinsic rates ranging from 30 to 45 beats/min. Under pathologic conditions, other atrial and ventricular tissues may pace the heart at varying rates. Impulses from the SA node are propagated through the atrial tissue to the AV node. Atrial depolarization is characterized by the P wave on the surface electrocardiogram (ECG; Fig. 69.4).

The AV node is an area of conduction tissue separating the atria and the ventricles, located in the posterior-inferior region of the interatrial septum. Its blood supply is from a branch of the RCA in 90% of patients (right dominant) and from the LCA in the remaining 10% (left dominant). Transmission of impulses within the AV node is slower than in other parts of the conducting system (Table 69.1) because of a dependence on slow-channel ion influx for membrane depolarization. An accessory pathway refers to conduction tissue outside the AV node that forms an alternative, or bypass, tract between the atria and ventricles. The term *preexcitation* refers to early ventricular depolarization via an accessory pathway.

On the surface ECG, the time it takes for conduction of an impulse through the atria to the ventricles is represented by the PR interval, normally ranging from 0.10 to 0.20 second (see Fig. 69.4). Impulses originating in lower atrial tissues or accessory pathways often have a shortened PR interval. PR prolongation is usually a result of nodal or supranodal conduction system disease.

After passing through the AV node, impulses propagate to the His bundle onto the three main bundle branch fascicles—the right bundle branch (RBB), left anterior-superior bundle (LASB), and left posterior-inferior bundle (LPB). The RBB and LASB are typically supplied by the left anterior descending (LAD) artery, whereas the LPB may be supplied by the RCA or LCA. After conduction down the three main bundle branches, impulses are delivered to the Purkinje fibers, which propagate impulses to myocardial tissues in a swift and orderly fashion, allowing for coordinated ventricular contraction. If an impulse arrives prematurely, it may be conducted abnormally (termed aberrant, associated with bundles that are relatively refractory) or blocked (if the bundles are completely refractory).

On the surface ECG, the QRS complex represents ventricular depolarization (see Fig. 69.4), normally 0.09 second or less; a duration of 0.12 second or longer is abnormal. The T wave corresponds to ventricular repolarization and its duration depends, among other things, on the length of the cardiac cycle. The QT
Mechanisms of Dysrhythmia Formation

Enhanced automaticity refers to spontaneous depolarization in nonpacemaker cells or depolarization at an abnormally low threshold in pacemaker cells (Fig. 69.5). Classic examples of enhanced automaticity include the idioventricular rhythms of severe hyperkalemia or myocardial ischemia and the atrial and junctional tachycardias (JTs) associated with digitalis toxicity.

Triggered activity refers to abnormal impulse(s) resulting from afterdepolarizations. Afterdepolarizations are fluctuations in membrane potential that occur as the resting potential is restored. These fluctuations may precipitate another depolarization just before full resting potential is reached (early afterdepolarizations) or after full resting potential is reached (delayed afterdepolarizations). The classic dysrhythmia associated with early afterdepolarization is acquired torsades de pointes, which typically arises in the setting of a prolonged QT interval and a new metabolic or drug trigger. Delayed afterdepolarizations classically arise in the setting of rapid heart rates and intracellular Ca\(^{2+}\) overload, as seen with digitalis toxicity or reperfusion therapy for acute myocardial infarction.

Reentry dysrhythmias arise from repetitive conduction of impulses through a self-sustaining circuit (Fig. 69.6). To maintain a reentry circuit, one conduction pathway must have a longer refractory period than the other, so that when an impulse exits one limb of the circuit, it may then reenter the other in retrograde fashion. The cycle is then repeated, creating a self-sustaining dysrhythmia. Reentry mechanisms are responsible for most narrow-complex tachycardias and many ventricular tachycardias (VTs). Treatment is predicated on altering conduction in one or both limbs of the circuit.

CLASSIFICATION OF ANTIDYSRHYTHMIC DRUGS

The four classes of antidysrhythmic medications are categorized according to their electrophysiologic effects (Box 69.1). Class I agents exert their major effects on the fast Na\(^{+}\) channels, resulting in membrane stabilization. The subclasses IA, IB, and IC have differing effects on depolarization, repolarization, and conduction. Class II agents are the β-adrenergic antagonists, which depress SA node automaticity, slow AV node conduction, and suppress conduction in ischemic myocardial tissue. Class III agents prolong repolarization and refractory period duration, predominantly via their effects on K\(^{+}\) channels. Class IV agents are the Ca\(^{2+}\) channel blockers, which slow conduction through the AV node and suppress other calcium-dependent dysrhythmias. Other agents important in the emergency treatment of dysrhythmias include magnesium sulfate, digitalis, and adenosine.

interval represents the total time of ventricular depolarization and repolarization and is altered by inherent physiologic abnormalities, metabolic changes, drugs, or structural changes. This interval is key to assess for QT prolongation in any patient with syncope or ventricular dysrhythmia, given the link to ventricular dysrhythmia recurrence.

**Mechanisms of Dysrhythmia Formation**

Enhanced automaticity refers to spontaneous depolarization in nonpacemaker cells or depolarization at an abnormally low threshold in pacemaker cells (Fig. 69.5). Classic examples of enhanced automaticity include the idioventricular rhythms of severe hyperkalemia or myocardial ischemia and the atrial and junctional tachycardias (JTs) associated with digitalis toxicity.

Triggered activity refers to abnormal impulse(s) resulting from afterdepolarizations. Afterdepolarizations are fluctuations in membrane potential that occur as the resting potential is restored. These fluctuations may precipitate another depolarization just before full resting potential is reached (early afterdepolarizations) or after full resting potential is reached (delayed afterdepolarizations). The classic dysrhythmia associated with early afterdepolarization is acquired torsades de pointes, which typically arises in the setting of a prolonged QT interval and a new metabolic or drug trigger. Delayed afterdepolarizations classically arise in the setting of rapid heart rates and intracellular Ca\(^{2+}\) overload, as seen with digitalis toxicity or reperfusion therapy for acute myocardial infarction.

Reentry dysrhythmias arise from repetitive conduction of impulses through a self-sustaining circuit (Fig. 69.6). To maintain a reentry circuit, one conduction pathway must have a longer refractory period than the other, so that when an impulse exits one limb of the circuit, it may then reenter the other in retrograde fashion. The cycle is then repeated, creating a self-sustaining dysrhythmia. Reentry mechanisms are responsible for most narrow-complex tachycardias and many ventricular tachycardias (VTs). Treatment is predicated on altering conduction in one or both limbs of the circuit.

**CLASSIFICATION OF ANTIDYSRHYTHMIC DRUGS**

The four classes of antidysrhythmic medications are categorized according to their electrophysiologic effects (Box 69.1). Class I agents exert their major effects on the fast Na\(^{+}\) channels, resulting in membrane stabilization. The subclasses IA, IB, and IC have differing effects on depolarization, repolarization, and conduction. Class II agents are the β-adrenergic antagonists, which depress SA node automaticity, slow AV node conduction, and suppress conduction in ischemic myocardial tissue. Class III agents prolong repolarization and refractory period duration, predominantly via their effects on K\(^{+}\) channels. Class IV agents are the Ca\(^{2+}\) channel blockers, which slow conduction through the AV node and suppress other calcium-dependent dysrhythmias. Other agents important in the emergency treatment of dysrhythmias include magnesium sulfate, digitalis, and adenosine.

**Class IA Agents**

Class IA agents slow conduction through the atria, AV node, and His-Purkinje system and suppress conduction in accessory pathways. Class IA agents also exhibit anticholinergic and mild negative inotropic effects.

**Procainamide**

Procainamide is the most commonly used class IA agent in the emergency treatment of ventricular and supraventricular dysrhythmias, and it can alter normal and accessory pathway conduction. In stable patients, the recommended administration is a rate of 20 to 30 mg/min until the dysrhythmia is terminated, hypotension occurs, or the QRS complex widens (to 50% of the pretreatment width), up to a total dose of 18 to 20 mg/kg (12 mg/kg if congestive heart failure is present). Procainamide triggers hypotension from vasodilatory effects in 5% to 10% of patients. Other class IA agents are not currently in use for acute care.

**Class IB Agents**

Class IB agents slow conduction and depolarization less than other class I agents, and they shorten repolarization rather than prolonging it. Class IB agents have little effect on accessory pathway conduction.

**Lidocaine**

Lidocaine is the sole class IB agent used in emergency rhythm management. Lidocaine can suppress dysrhythmias from enhanced automaticity, such as VT. Lidocaine also suppresses SA and AV node function and is associated with asystole in the setting
CHAPTER 69  Dysrhythmias

Class IC Agents

The class IC agents profoundly slow depolarization and conduction. More than any other class, these agents are associated with prodysrhythmia, the creation of a new ventricular dysrhythmia; this potential exists with class IA agents albeit much less. Class IC agents are approved only for oral use in the United States.

Flecainide

Flecainide is a class 1C antidysrhythmic agent used for paroxysmal supraventricular tachycardia and certain forms of VT. Flecainide has high oral bioavailability, variable half-life, and narrow therapeutic index, all hampering its use. Flecainide is not recommended for patients with ischemic or structural heart disease.

Propafenone

Propafenone shares electrophysiologic properties with classes IA and IC agents and possesses some β-adrenergic and calcium channel-blocking properties. Oral propafenone is used to prevent of acute myocardial ischemia. Currently, lidocaine is a second-line agent in ventricular tachycardia due to lower conversion rates compared to other agents. It also may have a role in prophylaxis from recurrent dysrhythmias in those surviving out-of-hospital ventricular fibrillation, although experimental data are limited.
atrial fibrillation and ventricular dysrhythmias. Like flecainide, this is used with caution in patients who have ischemic and/or structural heart disease.

**Class II Agents**

Class II agents—β-adrenergic blockers—suppress SA node automaticity and slow conduction through the AV node. Because of their effect on AV node conduction, class II agents are well suited to control the ventricular rate in patients with atrial tachydysrhythmias and can be useful to terminate AV nodal reentrant tachycardias (AVNRTs). In the setting of acute myocardial ischemia, beta blockers play a role in preventing ventricular dysrhythmias.

All beta blockers are active at β₁ and β₂ receptors (Table 69.2) to varying degrees. Those with more prominent β₁ effects are called cardioselective. Relative contraindications to the use of beta blockers include asthma or chronic obstructive lung disease, advanced congestive heart failure, and third-trimester pregnancy. Beta blockers should not be used in patients with preexisting bradycardia or heart block beyond first-degree. Acute side effects of beta blockers include bronchospasm, heart failure, excessive bradycardia, and hypotension. Intravenous (IV) beta blockers can trigger additive side effects when used in conjunction with calcium channel blockers, notably hypotension or bradycardia.

**Esmolol**

Esmolol is a β₁-selective agent useful in the emergency setting because of its rapid onset of action and short elimination half-life (minutes). Common dosing of esmolol is an IV bolus of 500 µg/kg followed by a continuous infusion beginning at 50 µg/kg/min and titrating to need and effect.

**Metoprolol**

Metoprolol is available in oral and IV preparations. Although not approved for dysrhythmia treatment in the United States, metoprolol (5–10 mg IV every 10–15 minutes in an adult, titrated to response) will slow atrial and nodal tachycardias.

**Class III Agents**

All class III agents prolong the refractory period primarily by blocking K⁺ channels, with variable effects on the QT interval. In
general, class III agents are alternatives to class I agents for the treatment of many ventricular and atrial dysrhythmias.

**Bretylium**

Bretylium was once the most commonly used class III agent. Due to its frequent hemodynamic side effects and limited effectiveness, bretylium is no longer available in the United States.

**Amiodarone**

Amiodarone is approved for the treatment of ventricular and supraventricular dysrhythmias and is the preferred choice for drug treatment of acute ventricular tachycardia. In addition to features in common with all class III agents, amiodarone has other effects, including actions that are similar to those of class IA, II, and IV agents.

</table>

**Classification of Antidysrhythmic Drugs**

**CLASS I**
Sodium (fast) channel blockers—slow depolarization with varying effects on repolarization. These drugs have membrane-stabilizing effects.

**Class IA**
Moderate slowing of depolarization and conduction; prolong repolarization and action potential duration.
- Procainamide
- Quinidine
- Disopyramide

**Class IB**
Minimally slow depolarization and conduction; shorten repolarization and action potential duration.
- Lidocaine
- Phenytoin
- Tocainide
- Mexiletine

**Class IC**
Markedly slow depolarization and conduction; prolong repolarization and action potential duration.
- Flecainide
- Encainide
- Lorcainide
- Propafenone (shares properties with class IA agents)
- Vernakalant (atrial-specific, investigational)

**CLASS II**
β-Adrenergic blockers
- Propranolol
- Esmolol
- Metoprolol
- Atenolol

**CLASS III**
Antifibrillatory agents—prolong action potential duration and refractory period duration with antifibrillatory properties.
- Bretylium (historical significance)
- Amiodarone
- Dofetilide
- Ibutilide
- Sotalol
- Dronedarone
- Azimilide

**CLASS IV**
Calcium (slow) channel blockers
- Verapamil
- Diltiazem

**MISCELLANEOUS**
- Digitalis
- Magnesium sulfate
- Adenosine

The serum half-life of amiodarone is 25 hours after a single IV dose and up to 50 days during long-term oral use. Because of its unusual pharmacokinetics, oral regimens vary widely. The acute side effects of amiodarone include hypotension, bradycardia, and heart failure (Box 69.2). There is an additive risk of bradycardia and hypotension when amiodarone is used in conjunction with calcium channel or β-adrenergic blockers. Rates of prodysrhythmia are relatively low. Long-term amiodarone use is associated with extracardiac side effects, including irreversible lung and thyroid disease. Amiodarone alters the pharmacokinetics of numerous other drugs, including digoxin and warfarin.

**Ibutilide**

Ibutilide has a unique mechanism of action characterized by the induction of a slow inward Na\(^{+}\) current, thereby prolonging the refractory period. IV ibutilide is approved for cardioversion of atrial fibrillation and atrial flutter. Because of QT prolongation and the risk of polymorphic VT, most health care providers choose to start ibutilide only in a monitored setting.

**Sotalol**

Sotalol is a β-adrenergic receptor blocker with type III antidystrhythmic properties. It is used orally for the suppression of supraventricular and ventricular dysrhythmias. Like ibutilide, start sotalol should be started in a monitored setting, watching for QT prolongation; it has a very limited role in emergency care.

**Dofetilide**

Dofetilide is a powerful class III agent approved for chemical cardioversion and maintenance of sinus rhythm in patients with...
Verapamil

IV verapamil is rarely used today given the advent of diltiazem, although still effective. If used, start at a dose of 0.1 mg/kg over 1 to 2 minutes; for the average healthy adult, this translates to a dose of 5 to 10 mg, which can be repeated or increased by 50% if unsuccessful and there is no hypotension 10 minutes after administration. In older adults or those with borderline hypotension (systolic blood pressure of 90–110 mm Hg), use a smaller dose (0.05 mg/kg or 2.5-mg increments).

Dronedarone

Structurally related to amiodarone, dronedarone displays class III properties in addition to those of other antidysrhythmic classes. Dronedarone is approved for oral use to maintain sinus rhythm in patients with atrial fibrillation or flutter but is contraindicated in patients with severe or recent heart failure. It has no current role in emergency care.

Class IV Agents

Class IV agents block slow Ca\(^{2+}\) channels, slowing conduction within the AV node and suppressing the SA node to a lesser degree. Like beta blockers, these are used in patients with supraventricular tachycardia.

All class IV agents are associated with peripheral vasodilation. Verapamil has the least effect on peripheral vascular tone, and diltiazem has an effect between that of verapamil and purely peripherally acting calcium channel blockers (e.g., nifedipine). In the acute setting, IV calcium salts (1 g, slow IV delivery) attenuate these peripheral vasodilatory effects. Class IV drugs should not be administered to patients with second- or third-degree AV block unless a functional pacemaker is in place and should be avoided in patients with first-degree block.

Diltiazem

IV diltiazem dosing is a 0.25- to 0.35-mg/kg bolus over 2 minutes. For longer term rate control, a continuous infusion (5–15 mg/hr initially, then titrated to need) or an oral dose (60–90 mg immediate-release formulation initially) will sustain the response.
Adenosine

Adenosine is a naturally occurring purine nucleoside that is the best choice for the termination of regular, nonatrial, narrow-complex tachydysrhythmias, notably junctional reentry. Administered as an IV bolus, adenosine causes an abrupt slowing of AV conduction in anterograde and retrograde pathways. Adenosine has an onset of action of 5 to 20 seconds and a duration of effect of 30 to 40 seconds. Except in rare cases, adenosine has little or no effect on infranodal conduction pathways. For this reason, adenosine is an option as a diagnostic (and sometimes therapeutic) agent in patients with wide-complex tachydysrhythmia when the cause is unclear.

Start adenosine by using a 6-mg rapid IV bolus (large, nondistal vein followed by a rapid flush) in for adults (≥250 kg body mass); key is the rapid bolus technique, with higher success noted after training to adhere to that tenet of delivery.4 If no response is seen within 1 to 2 minutes, increase the dose to a 12-mg IV bolus. If no effect is seen after a second 12-mg dose, then reassess the rhythm and use another therapy. There is no benefit to repeating adenosine when transient lowering is seen after a dose is given, followed by a return to the previous rhythm. Pediatric doses are 0.05 mg/kg initially, with doubling at similar intervals, up to a total dose of 0.25 mg/kg.

Side effects occur in up to one-third of patients given adenosine and are usually minor and self-limited. These include flushing, dyspnea, chest pressure, nausea, headache, dizziness, transient bradycardia or heart block, and hypotension. Asystole is possible but generally transient.

Because of its short duration of action, adenosine is not an effective rate control agent for atrial fibrillation or flutter, although it can help unmask these rhythms when not apparent on the initial surface ECG.

**APPROACH TO DYSRHYTHMIA: RECOGNITION AND MANAGEMENT**

**Clinical Features**

Dysrhythmias are classified according to their electrophysiologic origin, appearance on the ECG, and underlying ventricular rate. Although overlap exists, the following categorization is useful:

- **Bradyarrhythmias**
- **Extrasystoles**
- **Narrow-complex (QRS < 0.12 second) tachycardias** (regular and irregular)
- **Wide-complex (QRS ≥ 0.12 second) tachycardias** (regular and irregular)

Classically, the approach to any specific dysrhythmia is broadly defined based on clinical stability, which is driven by the effect on perfusion. Clearly unstable patients have severe or multiple end-organ features of hypoperfusion, such as altered sensorium, respiratory distress, hypotension, syncope, and/or chest pain suggestive of myocardial ischemia. Stable patients may be asymptomatic or have mild symptoms, such as lightheadedness, dyspnea on exertion, palpitations, and/or mild anxiety. In practice, clinical stability is a continuum; in the absence of profound altered sensorium or hypotension, a clear line distinguishing stable and unstable patients is often not present. One simple axiom is important:

- **Clearly unstable patients** with a primary dysrhythmia outside of a clear external trigger (eg, bradycardia for hypothermia or tachycardia for hypovolemic or distributive shock) need prompt electrical therapy—a countershock if there is a fast rate with a pulse and cutaneous pacing if there is a slow rate with a pulse.

Care of patients with cardiac arrest (those with no pulse) is covered elsewhere in this text (see Chapter 8).

A key consideration is whether a dysrhythmia is the cause or effect of a clinical presentation; for example, rapid atrial fibrillation may cause hypotension or may be a response to volume depletion or ischemia. Failure to consider the clinical situation can lead to an inappropriate treating of the rhythm to the detriment of the patient (eg, giving a rate-slowing agent when the tachycardia is a response to volume depletion). Recognizing this potential, treatment of patients who are clearly unstable and with a dysrhythmia is best done assuming that the rhythm is the cause. In a stable patient, a more systematic approach should be used to identify the cause and choose the most appropriate therapy.

**Initial Assessment of Stable Patients**

The approach begins with gathering evidence from the history, physical examination, and 12-lead ECG with a rhythm strip. The nature of any symptom is important, including the timing, velocity of onset (gradual vs. abrupt, with the latter often re-entrant based), and duration. For the patient with palpitations, questions about the rate and regularity of the heartbeat are often asked, and having the patient tap out the rhythm with a finger can aid. Other important questions are about precipitating events and associated symptoms, such as dizziness, chest pain, dyspnea, and/or syncope. The past history—notably of rhythm disturbances, ischemic or structural heart disease—and a medication history may raise a concern for specific rhythms. For example, a new and symptomatic wide-complex tachycardia in a patient with known ischemic heart disease is much more often VT than a supraventricular dysrhythmia. Occasionally, the family history helps, particularly if there are first-degree relatives with a history of dysrhythmia, unexplained syncope, or sudden death—all of which suggest an inherited disorder, such as an accessory pathway or Brugada’s syndrome.

Aside from palpating the pulse and listening to the heart sounds, the physical examination should be focused on detecting evidence of end-organ hypoperfusion (eg, agitation or confusion) or clues to an underlying cause of the dysrhythmia (eg, left ventricular failure). Observing the patient’s rhythm on a continuous cardiac monitor while he or she reports symptoms can add valuable information.

**DIAGNOSTIC CONSIDERATIONS**

**Differential Diagnosis**

**Diastolic Dysrhythmias**

**Differential Diagnosis**

**Diagnostic Testing**

The 12-lead ECG is essential to evaluating any patient with a suspected dysrhythmia. Use of a single ECG lead is often adequate for diagnosis, especially in unstable patients; multiple leads are optimal in stable patients. The latter helps detect as the presence or absence of P waves (often best seen in inferior leads or V1-2; Fig. 69.8), the relationship between P waves and QRS complexes, prolongation of the QRS and QT interval, and evidence of ischemia or prior myocardial infarction (Box 69.4). For certain conditions, such as Brugada’s syndrome, the 12-lead ECG, together with a history of syncope, is diagnostic. Because useful information
**BOX 69.4**

**Basic Electrocardiographic Observations During Dysrhythmia Analysis**

1. Ventricular rate—fast (>100 complexes/min), slow (<60 complexes/min), or normal (60–100 complexes/min).
2. Rhythm—regular, completely irregular (irregularly irregular or chaotic), regular with occasional irregularity, or grouped impulses; calipers, long strips help detect subtle irregularities.
3. QRS width—prolonged (>0.12 s), borderline (0.09–0.12 s), or normal. If determined without electrocardiogram being physically present (eg, prehospital radio medical command), ask for QRS duration in “number of small boxes” from printed rhythm strip (each box = 0.04 s) to ensure accuracy.
4. P wave presence and relationship to QRS complexes—May require mapping of P waves with calipers to detect those falling within QRS complex or T wave.
5. Rhythm changes—examine these areas closely for clues.
6. Multiple leads, especially chest leads or esophageal lead if difficulties with P wave visualization are experienced.
7. Comparison with previous tracings (if available) is often valuable.

About paroxysmal dysrhythmias is at the onset or termination of the rhythm, inspect those areas carefully and save the strip(s) for future reference.

Maneuvers that alter autonomic tone target relative increases in parasympathetic tone through the vagus nerve to help expose certain dysrhythmias and terminate others. In the ED, these maneuvers often fail, likely from a selection bias (easy responders terminate before arrival) or poor clinical technique. Vagal maneuvers, such as carotid sinus massage and the Valsalva maneuver, transiently slow AV conduction, which may help terminate or uncover a supraventricular rhythm disturbance. The key to using physical methods of enhancing parasympathetic tone is to optimize technique—have the patient lie flat, lift the legs, and ask for a Valsalva effort, with or without massage, to enhance success.

A nodal reentrant tachycardia may terminate abruptly with vagal maneuvers, whereas it often temporarily slows the ventricular rate in those with atrial fibrillation or atrial flutter; VT patients rarely have any change after vagal maneuvers. Auscultate the neck before carotid sinus massage, particularly in older patients, and avoid the maneuver if any are found or previous carotid disease is likely. Vagal maneuvers are frequently unsuccessful in the ED, but will rarely result in clinical deterioration. Poor technique often impairs massage-based maneuvers—for example, not...
having the patient supine or incorrect massage of the carotid artery instead of the carotid body. Other vagotonic maneuvers, such as rectal or ocular massage and ice water head dunking, are impractical and less effective.

**MANAGEMENT**

**Sinus Bradycardia and Sinoatrial and Atrioventricular Block**

Bradycardia is defined as a ventricular rate of less than 60 beats/min, although in practice rates above 50 beats/min are not usually a concern. Bradycardia occurs because of depression of the sinus node or because of a conduction system block; when the rate falls below a particular threshold, a subsidiary pacemaker elsewhere in the atrium, AV junction, or ventricle may assume the dominant role, resulting in an escape rhythm.

**Sinus Bradycardia**

Sinus bradycardia is characterized by a P wave with normal morphology, a fixed P-P interval equal to the R-R interval, and a ventricular rate below 60 beats/min (Fig. 69.9). This pattern may be found in healthy individuals, particularly well-conditioned athletes or young adults with a high resting vagal tone. Sinus bradycardia occurs in a variety of pathologic conditions associated with vagal stimulation, ranging from autonomic-mediated syncope to hemoperitoneum or acute inferior wall myocardial infarction. Other pathologic causes of sinus bradycardia include hypothermia, hypoxia, drug effects (especially β-adrenergic blockers and calcium channel blockers), and intrinsic sinus node disease (ie, sick sinus syndrome; see later). When sinus bradycardia drops below 40 beats/min, a junctional escape rhythm often emerges.

Sinus bradycardia is often asymptomatic and requires no specific treatment. If needed, first-line treatment for symptomatic sinus bradycardia in adults is atropine, a 0.5-mg IV bolus, repeated as needed every 3 to 5 minutes, to a total dose of 3 mg. Occasionally, a second-line agent such as dopamine or epinephrine infusion is needed. Emergency cutaneous pacing for sinus bradycardia is rarely indicated.

**Sinus Dysrhythmia**

Sinus dysrhythmia is a manifestation of the natural variation in heart rate that occurs during the respiratory cycle, manifested on the surface ECG as normally conducted P waves with a variable P-P interval (Fig. 69.10). It is a normal variant and is seen frequently in children and young adults.
Sinus Arrest and Sinoatrial Exit Block

A lack of atrial depolarization can occur because of failure of the sinus node to generate an impulse (sinus arrest) or failure of impulse conduction out of the SA node (SA exit block; Fig. 69.11). With SA exit block, it is not uncommon to see dropped P waves in regularly occurring patterns, representing 2:1, 3:1, or 4:1 block. Sinus arrest and SA exit block may be manifestations of intrinsic SA node disease, but can also be seen under conditions of increased vagal tone, whether benign or pathologic. When symptomatic, the approach to treatment is similar to that for sinus bradycardia.

Sick Sinus Syndrome

Sick sinus syndrome (SSS) is a group of dysrhythmias caused by disease of the sinus node and its surrounding tissues, creating sinus bradycardia, sinus arrest, or SA exit block. A variant of SSS known as bradycardia-tachycardia syndrome is characterized by one or more of these bradydysrhythmias alternating with a tachydysrhythmia, typically atrial fibrillation. SSS is most common in older adults, a result of fibrotic degeneration. It is also associated with cardiomyopathies, connective tissue diseases, and certain drugs. In the acute setting, treat the specific rhythm, although be wary about a profound subsequent bradycardia that could require temporary pacing following the use of a nodal blocking agent (especially a calcium channel blocker) for the tachycardic presentation. Long-term management requires permanent pacemaker placement for symptomatic bradycardia to allow for pharmacologic therapy for atrial fibrillation.

Atrioventricular Block

AV block results from impaired conduction through the atria, AV node, or proximal His-Purkinje system. First- and second-degree AV blocks represent partial impairment of conduction, whereas third-degree block indicates complete interruption. Advanced or high-grade AV block refers to AV block resulting in a ventricular rate that is pathologically slow.

First-Degree Atrioventricular Block

First-degree AV block is from prolonged conduction at the level of the atria, AV node (most common), or His-Purkinje system. On the ECG, first-degree AV block shows a prolonged PR interval (>0.20 second), typically with a narrow QRS complex (Fig. 69.12). First-degree AV block is a normal variant in up to 2% of healthy young adults. First-degree AV block requires no specific treatment other than avoiding any prolonged nodal blocking agents.

Second-Degree Atrioventricular Block

Second-degree AV block is when one or more (but not all) atrial impulses fail to reach the ventricles. The conduction ratio is the number of P waves to the number of QRS complexes over a period of time (eg, 3:2, 2:1). In circumstance in which the atrial rate is unusually fast—atrial flutter, for example—a conduction ratio of 2:1 may be physiologic, reflecting the normal refractory period of the AV node. However, in most other cases, a conduction ratio more than 1:1 is pathologic. Second-degree AV block is classified
into two types on the basis of the underlying pathophysiology and appearance of the ECG (Table 69.3).

**Type I Second-Degree Atrioventricular Block.** Type I second-degree AV block, also called Wenckebach or Mobitz I AV block, is associated with progressive impairment of conduction within the AV node. The surface ECG shows a lengthening of the PR interval from beat to beat until a P wave is entirely blocked (so-called dropped beat). This pattern gives the appearance of successive P waves retreating into the preceding QRS complexes (Fig. 69.13). Grouped beating (eg, pairs, trios) occurs and is not unique to type I second-degree AV block (Box 69.5).

Type I second-degree AV block occurs in a variety of conditions, benign and pathologic; often, these are associated with increased vagal tone and do not require specific treatment. In the setting of an acute myocardial infarction, type I second-degree AV block is generally transient and associated with a good outcome.

*Primarily refers to conduction ratio.
AV, Atrioventricular.

**Type II Second-Degree Atrioventricular Block.** Type II second-degree AV block, or Mobitz II block, is a conduction block just below the level of the AV node. On the surface ECG, conduction of atrial impulses is sporadic and typically periodic, but the PR interval does not widen from beat to beat (Fig. 69.14). The QRS complex is usually narrow, but concomitant infranodal conduction disturbances (ie, bundle branch blocks) can be seen in those with type II second-degree AV block.

Type II second-degree AV block can occur at conduction ratios similar to those seen with type I second-degree block but can also occur at higher conduction ratios (eg, 3:1, 4:1, or higher). When the conduction ratio is exactly 2:1, it is hard to distinguish type I from type II second-degree AV block on the surface ECG. In general, the presence of a prolonged PR interval makes type I block more likely, whereas the presence of wide QRS complexes makes type II block more likely.

Type II second-degree AV block arises as a result of senescent degeneration, drug toxicity, ischemia, or other pathologic conditions; it generally carries a worse prognosis than type I second-degree AV block. In acute myocardial infarction, type II second-degree AV block is associated with anterior wall injury and is often a precursor to complete AV block. No specific therapy is needed, aside from ensuring that pacemaking capability is immediately available.

**Third-Degree Atrioventricular Block**

Third-degree AV block, also known as complete heart block, is absent conduction of any atrial impulses (Fig. 69.15). Complete heart block is typically accompanied by a slow escape rhythm, with the width and frequency of QRS complexes depending on the site of the escape rhythm pacemaker. Pacemakers above the His bundle are associated with a narrow-complex QRS at a rate of 45 to 60 beats/min, whereas pacemakers at or below the His bundle produce a wide-complex QRS at a rate of 30 to 45 beats/min.

**Box 69.5**

**Causes of Grouped Impulses**

Wenckebach mechanism (usually at atrioventricular node, but can occur elsewhere)
Sinoatrial exit block
Atrial tachycardia or flutter with alternating conduction
Frequent extrasystoles
Nonconducted atrial trigemini
Concealed or interpolated extrasystoles
The hallmark of complete heart block is AV dissociation (i.e., no electrocardiographic relationship between P waves and QRS complexes), with an R-R interval longer than the P-P interval. Conversely, the presence of AV dissociation with an R-R interval shorter than the P-P interval (e.g., as occurs with accelerated junctional rhythms and VTs) does not imply third-degree heart block. When the atrial rate and the escape rates are similar (termed isorhythmic), detecting AV dissociation may require a long rhythm strip to track the P waves and QRS complexes. When complete heart block occurs in the presence of atrial fibrillation, the fibrillatory atrial waves are accompanied by a slow and regular ventricular response (so-called regularized atrial fibrillation). This specific dysrhythmia is classically associated with digitalis toxicity.

Third-degree AV block can be congenital but is usually acquired because of senescent degeneration of the electrical conduction system or as a result of acute ischemia, drug therapy, or other pathologic conditions (e.g., Lyme or Chagas’ disease).

In the ED setting, management of type II second-degree or complete AV block depends on the cause and presence of symptoms. Patients with newly acquired or symptomatic advanced AV block should be admitted to the hospital; in those who are markedly symptomatic (i.e., signs of hypoperfusion at rest), temporary transcutaneous or transvenous pacing should be started until the reversible cause can be treated (e.g., ST elevation myocardial infarction, beta blocker overdose) or a permanent pacemaker is placed. Atropine is usually ineffective.

**Extrasystoles**

An extrasystole is an electrical impulse originating from an ectopic atrial or ventricular focus. Depending on the site of origin and timing of the impulse, there may not be an associated mechanical contraction. The terms premature atrial contraction and premature ventricular contraction are widely used but are misleading, because contraction may not occur with the extra electrical activity seen on the ECG. The extrasystole and its preceding impulse are the couplet, and the coupling interval is the period between these two beats. Bigeminy (Fig. 69.16) occurs when there is an extrasystole after every native beat, so that every other impulse is extrasystolic; trigeminy (every third beat) and quadrigeminy (every fourth beat) are similar. Most extrasystoles are the result of enhanced automaticity from the atria, AV node, His-Purkinje system, or ventricles.
**Premature Atrial Contractions**

Premature atrial contractions (PACs; Fig. 69.17) are common and usually have little clinical significance. PACs on the ECG are an abnormal P wave early within a cardiac cycle, although sometimes the P wave may be difficult to detect if it is buried within the preceding T wave.

Most PACs will depolarize the sinus node, resetting its refractory period. Because of this, the P-P interval between two sinus beats surrounding a PAC will be less than twice the intrinsic P-P cycle length (see Fig. 69.17). If a PAC reaches the AV node or infranodal conducting system during its absolute refractory period, there will be no ventricular depolarization. A nonconducted (or blocked) PAC typically results in a noncompensatory pause (ie, R-R interval less than twice the intrinsic R-R cycle; Fig. 69.18) because the sinus node is reset. Blocked PACs are a common cause of electrocardiographic pauses and can be easily overlooked. On occasion, a PAC can be the precipitant of a more important dysrhythmia, such as atrial fibrillation, atrial flutter, or paroxysmal supraventricular tachycardia (PSVT).

If a PAC reaches the infranodal conducting system during its relative refractory period, the QRS complex is widened (or aberrant), typically with an RBBB pattern. Because the refractory period depends on the previous cycle length, an early arriving PAC...
that follows a long cardiac cycle is more likely to be aberrantly conducted. PACs are benign and require no specific treatment, but they may accompany catecholamine excess, myocardial ischemia, heart failure, hyperthyroidism, or a metabolic abnormality.

### Premature Ventricular Contractions

Premature ventricular contractions (PVCs) occur in a wide variety of states. Occasional PVCs are common in healthy adults or conditions associated with catecholamine excess, such as pain, anxiety, and use of stimulants (eg, caffeine, nicotine, cocaine, amphetamines). Pathologic conditions associated with frequent PVCs include myocardial infarction, potassium or magnesium disturbances, and medication toxicity (notably any with sodium channel–blocking or sympathetic enhancing activity). Usually not requiring intervention, frequent PVCs may herald the onset of VT, especially in the setting of ST elevation myocardial infarction or in patients with a prolonged QT interval.

A PVC appears as a wide–QRS complex extrasystole without a preceding P wave (Fig. 69.19). Because retrograde conduction of a PVC rarely extends far enough to capture and reset the SA node, atrial impulses continue to arrive at the AV node at the intrinsic sinus rate. As a result, the R-R interval surrounding a PVC ends up being equal to exactly twice the intrinsic R-R interval length (see Fig. 69.19), a phenomenon termed a compensatory pause. Rarely, a PVC will capture the SA node, resulting in a noncompensatory pause, or will fail to capture the AV node, leaving the underlying rhythm completely unaffected (a so-called interpolated PVC; Fig. 69.20).

The morphology of a PVC depends on the origin of the impulse, with a left bundle branch block (LBBB) appearance resulting from an extrasystolic focus in the right ventricle, and vice versa. Multiform (or multifocal) PVCs come from more than one source and have variable morphologies. When a PVC occurs at or around the time that a supraventricular impulse is set to depolarize the ventricle, the result is a fusion QRS complex (Fig. 69.21).

Direct therapy for PVCs toward correcting any precipitating condition whether it is catecholamine excess, drug effect, electrolyte imbalance, or cardiac ischemia (Box 69.6). Often, PVCs do not require treatment in the ED. When occurring in isolation, treat symptomatic PVCs with a beta blocker (metoprolol, 5–10 mg IV or 25–50 mg PO), although this is rarely an emergent need. Although lidocaine suppresses PVCs, do not use it routinely in the absence of VT because of limited clinical benefit and the risk of asystole.

### Narrow-Complex Tachycardia

Narrow-complex tachycardias have a QRS complex duration of 0.12 second or less on the surface ECG and a ventricular rate more than 100 beats/min. The term supraventricular tachycardia may...
Alternatively, the patient may convert to sinus rhythm, in which case AVNRT can be diagnosed and treated.

Sinus Tachycardia

Sinus tachycardia displays a regular, usually narrow-complex tachycardia, with normal P waves preceding each QRS complex (Fig. 69.22) on the ECG. In adults, sinus tachycardia rarely exceeds a rate of 170 beats/min; in infants and young children, it is not unusual to see rates above 200 to 225 beats/min. Sinus tachycardia tends to speed up or slow down in a graded and continuous manner over time, relayed by history or observed under care.

Sinus tachycardia is often a response to physiologic stress or is a compensation for a relative lack of perfusion or oxygen delivery (to increase cardiac output). Usually, the effect is salutary, as seen with hypovolemia, anemia, or hypoxemia; efforts to slow the heart rate without addressing the underlying pathophysiology are likely to make things worse. At other times, sinus tachycardia is a counterproductive response, as in acute decompensated heart failure or aortic stenosis, in which a decrease in filling time further compromises cardiac output. Even in these settings, therapy is aimed first at the underlying problem rather than the tachycardia.

Sinus tachycardia can be seen with any sympathetic excess, whether endogenous (eg, pain, anxiety, fever, hyperthyroidism) or exogenous (eg, stimulants, other drugs). The approach to the patient with sinus tachycardia centers on identifying and addressing the cause(s).

Atrial Tachycardia

Atrial tachycardia (AT) is an atrial rhythm with more than 100 QRS complexes/min arising from a non–sinus node site(s) within the left or right atrium. The electrocardiographic hallmark of AT is morphologically abnormal P waves on the surface ECG, all or mostly related to each QRS wave (Fig. 69.23). If the site of origin is close to the sinus node, atrial depolarization waves may look like a normal P wave. Depending on the atrial rate, the AV conduction ratio may be 1:1, 2:1, or higher.

AT is common in children and young adults with structural heart disease, often precipitated by the occurrence of a PAC. The rhythm is usually transient and does not require specific therapy. AT can occur in patients with structural heart disease, hypoxemia, metabolic disturbances, and/or drug toxicity. In patients taking
hypomagnesemia, give supplemental magnesium (2 g IV over 5 minutes). Vagal maneuvers and adenosine are unlikely to be effective in AT or MAT, although these may help unmask the atrial activity. Pharmacologic therapy to slow AV conduction with a beta blocker or calcium channel blocker aids in the symptomatic but stable patient. Because AT and MAT are often precipitated by underlying illnesses, electrical cardioversion often fails or the rhythm recurs.

**Atrial Fibrillation**

Atrial fibrillation is identified by electrical chaos; it starts from unpatterned depolarization of atrial tissues caused by multiple digitalis, suspect toxicity if AT exists, particularly in the presence of 2:1 or higher grade AV block.

Multifocal atrial tachycardia (MAT) is a form of AT with three or more distinct P wave morphologies, and varying PR and P-P intervals from the multiple ectopic atrial foci (Fig. 69.24). MAT is associated with pulmonary disease (usually chronic obstructive pulmonary disease [COPD]) in up to 60% of cases, but can also be seen in the presence of primary cardiac pathology. On the surface ECG, MAT is often mistaken for atrial fibrillation because of the nonuniform atrial activity and irregular R-R intervals.

The approach to patients with AT is to identify and treat any precipitating factors, such as hypoxia or hypoxemia, electrolyte abnormalities, and drug toxicity. In patients with suspected hypomagnesemia, give supplemental magnesium (2 g IV over 5 minutes). Vagal maneuvers and adenosine are unlikely to be effective in AT or MAT, although these may help unmask the atrial activity. Pharmacologic therapy to slow AV conduction with a beta blocker or calcium channel blocker aids in the symptomatic but stable patient. Because AT and MAT are often precipitated by underlying illnesses, electrical cardioversion often fails or the rhythm recurs.
micreoreentry circuits, generating 300 to 600 atrial impulses/min. This chaotic activity reduces cardiac output from a loss of coordinated atrial contractions and from a rapid ventricular rate, both of which may limit the diastolic filling and stroke volume of the ventricles.

Atrial fibrillation is the most common sustained dysrhythmia, increasing with age; it affects 1% of the population older than 60 years and 5% of those 69 years old or more. Patients with atrial fibrillation can develop left atrial thrombi, especially in the left atrial appendage, and consequent embolic events. The risk of stroke is three to five times greater than in those without atrial fibrillation. Appendageal sequestration through transcatheter approaches may alter the need for long-term, clot-directed therapy to mitigate embolic risks, but empirical long-term data are absent. Also, ablation therapies may restore sinus rhythm without the need for ongoing drug therapy.

Atrial fibrillation may be paroxysmal (spontaneously converts), persistent (requires cardioversion to convert), or permanent (when no further efforts to restore sinus rhythm are planned). Long-term approaches to management depend on many factors, including chronicity, symptomaticity, underlying heart disease, and other comorbidities.

The electrocardiographic hallmark of atrial fibrillation is a so-called irregularly irregular QRS pattern (Fig. 69.25). Although atrial fibrillation is not the sole cause of an irregular ventricular rhythm, it is the most common (Box 69.7). Atrial fibrillatory waves appear coarse or fine on the basis of their amplitude and are often best appreciated in the inferior leads or lead V1.

Typically, the ventricular rate in adults with atrial fibrillation does not exceed 150 to 170 beats/min and often is slower, particularly in the presence of nodal blocking agents. Atrial fibrillation in an adult with a ventricular rate exceeding 200 beats/min strongly suggests the presence of an accessory conduction pathway and has important implications for management (see later). Frequently, rapid atrial fibrillation with an accessory path will have a wide QRS complex, but not always; if the irregularity of ventricular depolarization is not sought by the careful use of a caliper or similar measurement, it is easy to mistake this wide but chaotic rhythm for VT. When a wide QRS complex is seen at rates below 200 beats/min but with ventricular chaos, an existing or acquired bundle branch block with atrial fibrillation is likely present.

Atrial fibrillation may be paroxysmal (spontaneously converts), persistent (requires cardioversion to convert), or permanent (when no further efforts to restore sinus rhythm are planned). Long-term approaches to management depend on many factors, including chronicity, symptomaticity, underlying heart disease, and other comorbidities.

The electrocardiographic hallmark of atrial fibrillation is a so-called irregularly irregular QRS pattern (Fig. 69.25). Although atrial fibrillation is not the sole cause of an irregular ventricular rhythm, it is the most common (Box 69.7). Atrial fibrillatory waves appear coarse or fine on the basis of their amplitude and are often best appreciated in the inferior leads or lead V1.

Typically, the ventricular rate in adults with atrial fibrillation does not exceed 150 to 170 beats/min and often is slower, particularly in the presence of nodal blocking agents. Atrial fibrillation in an adult with a ventricular rate exceeding 200 beats/min strongly suggests the presence of an accessory conduction pathway and has important implications for management (see later). Frequently, rapid atrial fibrillation with an accessory path will have a wide QRS complex, but not always; if the irregularity of ventricular depolarization is not sought by the careful use of a caliper or similar measurement, it is easy to mistake this wide but chaotic rhythm for VT. When a wide QRS complex is seen at rates below 200 beats/min but with ventricular chaos, an existing or acquired bundle branch block with atrial fibrillation is likely present.

The Ashman phenomenon refers to aberrant ventricular conduction of an early-arriving atrial impulse following a relatively long R-R interval, the result of a partially refractory His bundle. Such aberrantly conducted impulses are commonly seen in atrial fibrillation but can occur in any irregular rhythm in which long-short cycle sequences occur; they typically assume an RBBB pattern (Fig. 69.26). Ashman beats can be mistaken for PVCs or paroxysmal VT, if sustained.

Atrial fibrillation is usually associated with underlying heart disease (myopathic or valvular) or hypertension (Box 69.8), but can also occur in isolation (so-called lone atrial fibrillation) or as
a manifestation of hyperthyroidism. As many as one-third of patients with congestive heart failure also have atrial fibrillation.

The presentation of patients with atrial fibrillation is variable. For example, patients without underlying cardiopulmonary disease may tolerate atrial fibrillation with ventricular rates of 150 to 170 beats/min, noting only palpitations or exercise intolerance. Conversely, a patient with left ventricular dysfunction and new or worsened rate control may experience dyspnea at rest. In a stable patient with preexisting atrial fibrillation and a new rapid ventricular rate, direct the initial evaluation at determining if the tachycardia is a response to some other hemodynamic stress, such as decompensated heart failure, sepsis, hypovolemia, massive pulmonary embolism, or cardiac tamponade. Failure to recognize the underlying cause of a new tachycardia may result in counterproductive attempts at rate control or cardioversion. Measuring the thyroid-stimulating hormone level is prudent in those with therapeutic anticoagulation, ED cardioversion is an option unless valve disease, hypokalemia, or digitalis toxicity exist; the latter two conditions increase the risk of ventricular fibrillation with any type of conversion therapy. 7-11 If atrial fibrillation has been present longer than 2 days or for an uncertain interval in the absence of ongoing anticoagulation, do not attempt cardioversion to avoid the increased risk of systemic embolization (1%-4% at 30 days).

The choice of electrical versus pharmacologic cardioversion is dependent on institutional factors and patient preference, although success rates are higher with electrical conversion (80%-95%).9,10 Among patients with new or recurrent atrial fibrillation of less than 48 to 72 hours duration, up to 50% will convert spontaneously to sinus rhythm within 24 hours. Patients with valvular disease fail cardioversion or recur frequently, limiting the ED options to rate control.

Various agents are available for the pharmacologic cardioversion of patients with stable atrial fibrillation in the ED, including the class IA, IC, and III antidysrhythmics (Box 69.9). In practice, IV procanamide, amiodarone, and ibutilide are the agents most commonly used in the ED setting. Amiodarone is commonly used because it initially slows the ventricular response without the need for an antecedent rate-controlling agent. Although there are differences in success rates among various agents, the overall response is 40% to 65% for drug-based ED cardioversion, although it may require up to 6 hours to occur. Do not use class IC antidysrhythmics in patients with structural or ischemic heart disease. For atrial fibrillation with accessory pathway conduction, use

Accessory pathway (Wolff-Parkinson-White syndrome)
procainamide as a first-line agent because it has no effect on AV conduction.

If choosing electrical cardioversion, obtain consent for the procedure and systemic sedation or analgesia needed. Rate-controlling agents before countershock are not required and may impair success.11 While closely monitoring the airway and cardiac responses, place the pads on the front and back of the chest and use 100 J, biphasic and unsynchronized preferred; occasionally, a second attempt at 100 to 200 J is required.

Many patients with atrial fibrillation, whether paroxysmal or permanent, benefit from long-term antiarrhythmic therapy to prevent conversion to sinus rhythm. The American Heart Association (AHA) and European Society of Cardiology recommend using the CHA2DS2-VASc score to guide clot prevention therapy in those with atrial fibrillation (Box 69.10).12 The choices include no therapy for the lowest risk strata (by definition those <65 years and without other features); aspirin (325 mg daily) for the next strata of patients who are still lower risk, and warfarin or one of the new oral direct thrombin inhibitors (eg, dabigatran, rivaroxaban, apixaban) for the remaining higher risk patients.12,13 Although long-term anticoagulation typically falls beyond the scope of the ED, starting therapy early can enhance compliance. Start outpatient anticoagulation therapy in the ED only after confirming close and timely follow-up.

Atrial fibrillation alone is not an indication for hospital admission. Observation or admission is best in symptomatic patients with atrial fibrillation complicated by underlying acute or exacerbated cardiopulmonary disease, for those where duration is unknown and follow-up uncertain, for those who fail cardioversion or the dysrhythmia returns, and in all patients with concomitant new noncardiac illnesses.

Atrial Flutter

Atrial flutter is characterized by atrial depolarization occurring at a regular rate of 250 to 350 beats/min (300 beats/min is typical) caused by an atrial reentry mechanism (Fig. 69.27). Flutter waves on the ECG are broad, sawtooth-appearing, regular depolarizations prior to QRS complexes, with the latter occurring at some fraction of the atrial rate. The ventricular rate in atrial flutter is often rapid, but in the absence of a bypass tract (in which 1:1 conduction is possible), the conduction ratio is limited by the refractory period of the AV node. With 2:1 conduction, the ventricular rate is approximately 150 beats/min, often making flutter waves difficult to appreciate and allowing the rhythm to be mistaken for sinus tachycardia. Because the atrial rate can vary, the classic ventricular rate of 150/min is not always present with atrial flutter. When the conduction ratio changes from beat to beat, this is termed atrial flutter with variable conduction, with a resultant irregular ventricular rate making it difficult to distinguish from atrial fibrillation.

Atrial flutter often accompanies pulmonary disease, structural heart disease, particularly valvular heart disease, and cardiomyopathies. The acute management of atrial flutter is similar to that of atrial fibrillation, with a few special considerations. Because AV conduction occurs at fixed ratios in atrial flutter, the administration of beta blocker or calcium channel blocker therapy can result in an abrupt rate change, making it more challenging to titrate therapy to a desired target rate.

Atrial flutter is more sensitive to DC cardioversion (up to 90% conversion rate) than atrial fibrillation, and usually requires lower energy (20–50 J) for conversion to sinus rhythm.13 Atrial flutter is more resistant to chemical cardioversion (<50% success) than new-onset, nonvalvular atrial fibrillation.

Atrioventricular Nodal Reentrant Tachycardia

Also known by the less precise term paroxysmal supraventricular tachycardia (PSVT, or just SVT), AVNRT is a regular, narrow-complex rhythm with a ventricular rate of 130 beats/min or greater, commonly more than 160 beats/min (Fig. 69.28). It is the most common non–sinus tachycardia in young adults. AVNRT is the result of a reentry circuit within the AV node, with normal conduction (narrow QRS) down the bundles of His and with retrograde conduction (inverted P waves typically buried within the QRS) up into the atria (Fig. 69.29).

The onset and spontaneous end of AVNRT is typically abrupt, and it frequently arises in the context of strenuous exercise or...
emotional stress. Most patients with AVNRT are symptomatic, but hemodynamic instability is unusual in the absence of underlying cardiopulmonary disease.

If vagal maneuvers fail to restore sinus rhythm, first-line field or ED therapy for AVNRT is adenosine\(^6\) (6 mg rapid, large-bore IV bolus followed by a flush; repeat with 12 mg if no effect on rate). This approach is successful in 85% to 90% of cases and is safe.\(^{17}\) In refractory cases, diltiazem, esmolol, or metoprolol are options. Rarely needed, synchronized cardioversion (at 100–200 J, synchronized and biphasic preferred) can terminate AVNRT refractory to pharmacologic therapy or in a patient with hemodynamic instability.

No specific laboratory testing is needed, although mild troponin level elevations occur but are of uncertain significance aside from other concerns for myocardial ischemia.\(^{18}\) Most patients can be discharged after terminating AVNRT with adenosine or vagal maneuvers and typically require no testing beyond an ECG, including in the field setting.\(^{19}\) Patients with frequent recurrences are candidates for prophylaxis (primarily with a beta blocker or calcium channel blocker) or ablation therapy. Starting rhythm control therapy from the ED is best only for those patients who have a secure follow-up plan known by their primary care provider.

**Junctional Tachycardia**

In contrast to the bursts seen in AVNRT, JTs (also known as nonparoxysmal or sustained JTs) show sustained ventricular rates but rarely exceed 130 beats/min. JTs are associated with structural heart disease, metabolic disturbances, or drug toxicity. Treatment is aimed at addressing underlying conditions, although a trial of nodal blockade with calcium or beta blockers is an option.

**Preexcitation and Accessory Pathway Syndromes**

The term *preexcitation* is depolarization of the ventricular myocardium via an accessory pathway (or bypass tract) linking the atria to the ventricles, circumventing the normal AV node. Accessory pathways do not have the so-called brakes or rate limits of the AV node, lending themselves to reentry tachycardia and
rapid ventricular rates. Wolff-Parkinson-White (WPW) syndrome is the classic accessory pathway syndrome, characterized by paroxysmal tachycardia and three resting electrocardiographic features (Fig. 69.30):

- Short PR interval (<0.12 second)
- QRS duration longer than 0.10 second
- Slurred upstroke to the QRS complex, referred to as a delta wave

Not all patients with WPW or other preexcitation syndromes have all the classic features on their surface ECG. Conversely, some patients with WPW-like patterns on their resting ECG never develop reentry tachycardia. Although some with WPW syndrome have structural disease, most patients have no other underlying cardiac abnormality (Box 69.11). Patients with WPW can develop atrial fibrillation, seen in up to 30% of patients with WPW.

**BOX 69.11**

**Diseases Associated With Wolff-Parkinson-White Syndrome**

- Idiopathic
- Cardiomyopathy (especially hypertrophic)
- Transposition of great vessels
- Endocardial fibroelastosis
- Mitral valve prolapse
- Tricuspid atresia
- Ebstein’s disease

*Most common.*
The presence of an accessory pathway can form a reentry circuit together with an AV nodal pathway to produce and sustain a rapid ventricular rate (Fig. 69.31). When the AV node is being used for anterograde conduction to the ventricles, and the accessory path is used for retrograde conduction, it is called an orthodromic AV-reentrant tachycardia—the QRS complex is typically narrow, and the ventricular rate is constrained by the refractory period of the AV node. Conversely, when the accessory pathway is being used as the anterograde limb and the AV node as the retrograde limb of the reentry circuit, it is called an antidromic AV-reentrant tachycardia—the QRS complex is wide and ventricular rates can be extremely rapid.

Orthodromic AV reentrant tachycardia is the most common presenting dysrhythmia in WPW syndrome and is indistinguishable clinically from AVNRT. Like AVNRT, treat orthodromic AV reentrant tachycardia with vagal maneuvers and adenosine as first-line therapy, followed by calcium channel blockers and beta blockers as second-line agents.

In contrast, antidromic AV reentrant tachycardia, with its characteristic wide QRS complexes, can have ventricular rates of 200 beats/min or more and clinical instability. When the typical QRS antidromic changes are coupled with tachycardia, AV nodal blocking agents are contraindicated to avoid degeneration into ventricular fibrillation. Similarly, in patients with a very rapid (>220/min) irregular tachycardia accompanied by a wide-complex QRS, do not use nodal blockade because of the risk of rapid deterioration to ventricular fibrillation from unbrided conduction down the accessory pathway. Procainamide is first-line therapy for tachycardia whenever the presence of wide QRS antidromic changes are coupled with tachycardia, AV nodal dissociation or fusion beats on the 12-lead ECG clearly points to VT; older age and a prior history of myocardial infarction make VT more likely than a supraventricular tachycardia with aberrancy. On the other hand, an irregular tachycardia with a wide QRS approximating a bundle branch morphology is most likely atrial fibrillation with aberrant conduction. For stable patients, there are decision tools that can be used to distinguish VT with relatively good accuracy (Table 69.5; Fig. 69.32). Although newborn VT patients are usually unstable, the presence of hemodynamic stability does not exclude VT.

Wide-complex tachycardia refers to any tachydysrhythmia accompanied by a QRS duration of 0.12 second or more. Wide-complex tachycardia can start in the ventricles (ie, ventricular tachycardia, VT) or can originate from above the AV node but be accompanied by aberrant AV conduction. The aberrant conduction is caused by an accessory pathway or a bundle branch block. The presence of AV dissociation or fusion beats on the 12-lead ECG clearly points to VT; older age and a prior history of myocardial infarction make VT more likely than a supraventricular tachycardia with aberrancy. On the other hand, an irregular tachycardia with a wide QRS approximating a bundle branch morphology is most likely atrial fibrillation with aberrant conduction. For stable patients, there are decision tools that can be used to distinguish VT with relatively good accuracy (Table 69.5; Fig. 69.32). Although newborn VT patients are usually unstable, the presence of hemodynamic stability does not exclude VT.

The Brugada ECG criteria describe four features of VT from among those described in the original Wellens criteria, any one of which makes the diagnosis of VT. The rhythm needs to be regular for these to be used, because irregularity suggests atrial fibrillation with altered conduction. The sequential criteria are as follows (Fig. 69.33; see Fig. 69.32): 1. Absence of any RS complexes in the precordial leads 2. RS duration (measured from beginning of R to deepest part of S wave) greater than 100 msec 3. AV dissociation (often present but overlooked; may be best appreciated in inferior limb leads and V6; Fig. 69.34) 4. Specific VT morphologic criteria (see Fig. 69.33)

The Lown-Ganong-Levine syndrome is an uncommon accessory pathway syndrome associated with paroxysmal narrow-complex tachycardia, short PR interval, and normal QRS complex without a delta wave. The treatment parallels that for the WPW syndrome.

The classic Wellens criteria are an example of time-honored but hard to use criteria because of their complexity and lack of order or weighting of findings. The Brugada ECG criteria describe four features of VT from among those described in the original Wellens criteria, any one of which makes the diagnosis of VT. The rhythm needs to be regular for these to be used, because irregularity suggests atrial fibrillation with altered conduction. The sequential criteria are as follows (Fig. 69.33; see Fig. 69.32): 1. Absence of any RS complexes in the precordial leads 2. RS duration (measured from beginning of R to deepest part of S wave) greater than 100 msec 3. AV dissociation (often present but overlooked; may be best appreciated in inferior limb leads and V6; Fig. 69.34) 4. Specific VT morphologic criteria (see Fig. 69.33)

The Grifith criteria use a three-step approach to identify aberrancy, first through classic RBBB or LBBB morphologies in V1 and V6 to identify an SVT and then seeking AV dissociation in the remainder to identify VT (see Figs. 69.32 and 69.34). This approach has a sensitivity of 92% with a lower specificity than that seen with the Brugada approach. There are no direct, in-practice comparative data between these two approaches. Finally, the Verecke criteria (Fig. 69.35) examine lead aVR to differentiate between VT and SVT; however, in practice, these have not been shown to be more effective or accurate, limiting their use.

Treat unstable patients with a wide-complex tachycardia with electrical cardioversion (100 J, synchronized and biphasic, if possible). For borderline patients, electrical cardioversion with
Fig. 69.30. A, Wolff-Parkinson-White (WPW) syndrome. B, WPW syndrome with atrial fibrillation. Note the short refractory period (330 ms). (A from Watanabe Y, Dreifus LS: Cardiac dysrhythmias, New York, 1977, Grune & Stratton.)
QRS complexes, usually in a regular pattern and at a rate of 150 to 200 beats/min (Fig. 69.36). Polymorphic ventricular tachycardia is seen with varying QRS morphologies and suggests more severe underlying disease (Figs. 69.37 and 69.38). VT is prevalent in patients with ischemic and nonischemic cardiomyopathy.

For stable patients with VT, amiodarone (3–5 mg/kg IV over minutes, often 250–350 mg) is the best choice, with reported successful termination of up to 90%. Procainamide (30–50 mg/min IV, up to a total of 18 mg/kg or until VT is terminated) is a second-line agent. Lidocaine (1.0- to 1.5-mg/kg IV bolus, up to 3 mg/kg maximum, and followed by an infusion) was the preferred choice in the past and is easy to deliver, but it was hampered by lower success rates and is now relegated to an alternative role.

Unstable patients or those with VT refractory to pharmacotherapy should undergo synchronized cardioversion with 100 J (biphasic preferred), with procedural sedation; escalating doses (up to 200 J biphasic or 360 J monophasic) are occasionally needed.

Seek expert consultation and admit all patients with new or symptomatic VT, with the exception of potential discharge after consultation for those who have properly functioning implanted defibrillators (see Chapter 80).

*If proven by electrophysiologic studies or by a preponderance of evidence.

bMain deflection of QRS complex either positive or negative in every precordial lead.

ASHD, Arteriosclerotic heart disease; AV, atrioventricular; CABG, coronary artery bypass graft; LAD, left anterior descending.

Systemic sedation or analgesia or pharmacologic treatment with procarbazine or amiodarone are options.

Adenosine is an option after a careful search of the ECG does not suggest VT. Do not use adenosine if you suspect VT or if there is an irregular or very rapid ventricular rate (≥250 beats/min). Most SVTs will slow or terminate with adenosine, and only rare VT forms respond; any ill effects of adenosine are usually fleeting. Other pharmacologic therapies for stable VT are discussed later. If pharmacologic treatment fails, synchronized cardioversion is an option.

**Ventricular Tachycardia**

VT originates within or below the His bundle. Nonsustained VT refers to short episodes (<30 seconds) reverting spontaneously, whereas sustained VT is more prolonged. Reentry mechanisms are the most common cause of VT, although automatic and triggered mechanisms occur. Most patients with VT have underlying heart disease.

Monomorphic ventricular tachycardia is the most common form of VT and is characterized by morphologically consistent QRS complexes, usually in a regular pattern and at a rate of 150 to 200 beats/min (Fig. 69.36). Polymorphic ventricular tachycardia is seen with varying QRS morphologies and suggests more severe underlying disease (Figs. 69.37 and 69.38). VT is prevalent in patients with ischemic and nonischemic cardiomyopathy.

For stable patients with VT, amiodarone (3–5 mg/kg IV over minutes, often 250–350 mg) is the best choice, with reported successful termination of up to 90%. Procainamide (30–50 mg/min IV, up to a total of 18 mg/kg or until VT is terminated) is a second-line agent. Lidocaine (1.0- to 1.5-mg/kg IV bolus, up to 3 mg/kg maximum, and followed by an infusion) was the preferred choice in the past and is easy to deliver, but it was hampered by lower success rates and is now relegated to an alternative role.

Unstable patients or those with VT refractory to pharmacotherapy should undergo synchronized cardioversion with 100 J (biphasic preferred), with procedural sedation; escalating doses (up to 200 J biphasic or 360 J monophasic) are occasionally needed.

Seek expert consultation and admit all patients with new or symptomatic VT, with the exception of potential discharge after consultation for those who have properly functioning implanted defibrillators (see Chapter 80).
Fig. 69.32. A, Brugada four-step approach for differentiating ventricular tachycardia (VT) and wide-QRS supraventricular tachycardia. Only when the response to all four questions is negative is a supraventricular rhythm with abnormal conduction diagnosed. As soon as a single “yes” answer is noted, VT is diagnosed. B, Griffith approach, in which aberrant conduction is sought in leads V₁ and V₆ (right bundle branch block [RBBB] or left bundle branch block [LBBB], classic appearances), followed by a search for atrioventricular (AV) dissociation. If classic RBBB and LBBB patterns are absent, or if the remainder of the leads have no AV dissociation, VT is diagnosed. (A from Brugada P, Brugada J, Mont L, et al: A new approach to the differential diagnosis of a regular tachycardia with a wide QRS complex. Torsades de Pointes

Torsades de pointes is literally translated as "twisting of the points" and is a paroxysmal form of polymorphic VT that meets the following clinical criteria (see Fig. 69.38):
1. Ventricular rate greater than 200 beats/min
2. Undulating QRS axis, with the polarity of the complexes appearing to shift about the baseline
3. Paroxysms of less than 90 seconds

Torsades de pointes occurs in the setting of a prolonged QT interval, a reflection of abnormal ventricular repolarization. A prolonged QT interval can be congenital or acquired. Women are at a greater risk for Torsades de pointes. Acquired Torsades de pointes is much more common than congenital and is pause-dependent, triggered by a slow heart rate.

Acquired QT prolongation is the most common form seen outside a specialized pediatric setting and usually has multifactorial causes (Box 69.12). Common triggers include electrolyte disturbances (eg, hypokalemia, hypomagnesemia) and many different drugs (notably class IA and IC agents but also many others; see Box 69.12), especially when used in combination.

Treatment of torsades de pointes in stable adult patients involves correcting any underlying metabolic or electrolyte abnormalities and increasing the heart rate to shorten ventricular repolarization. In patients with torsades de pointes, do not use class IA and IC antidysrhythmics. Empirical IV magnesium sulfate is effective in treating torsades de pointes, even in the absence of hypomagnesemia, and may prevent recurrence if electrical cardioversion succeeds.

A baseline ventricular rate of 100 to 120 beats/min is usually enough to prevent acquired torsades de pointes, achieved by overdrive pacing (ie, external pacing at a rate greater than the patient’s intrinsic rate) or via β-adrenergic infusion. Use electrical cardioversion for unstable patients, as outlined in the discussion of VT with sustained torsades de pointes, without any attempt to synchronize.

Congenital torsades de pointes is rare and is triggered by sympathetic excess or tachycardia; it is usually seen in children and young adults. Patients often have syncope during exertion and a prolonged QT interval on the ECG. In contrast to acquired forms, treat congenital torsades de pointes with beta blockers.

Brugada’s Syndrome

Brugada’s syndrome is characterized by ventricular dysrhythmias triggering syncope or sudden cardiac death in the absence of structural heart disease. This syndrome is caused by an inherited disorder of sodium channels and is commonly diagnosed in men during young adulthood. The Brugada electrocardiographic pattern shows a downward coved or humped (saddleback) ST segment elevation in leads V1 to V3 (Fig. 69.39), sometimes simulating an RBBB appearance. The ST segment findings may be transient or elicited only with pharmacologic stimulation.

Any patient with unexplained syncope and a Brugada pattern ECG requires admission for consideration of an implanted defibrillator. For patients in whom a Brugada pattern ECG is noted incidentally, there is no consensus on treatment, but we recommend referral to a cardiologist.

**DISPOSITION**

Patients with dysrhythmias that are markedly symptomatic and nonresponsive to ED therapy require admission; in those without symptoms or only palpitations, and who resolve, with no evidence of structural heart disease, outpatient ambulatory monitoring and close contact with a cardiologist is an option. When evaluating anyone with symptomatic rhythm changes, we recommend a cardiology consultation. Those with VT or torsades de pointes, and most symptomatic patients with type II second-degree or complete heart block, require admission.
Fig. 69.36. Ventricular tachycardia. **A**, RS complexes are present in chest leads, but RS duration is greater than 100 ms. Although the Brugada criteria indicate that no further analysis is necessary, atrioventricular dissociation is also evident, and QRS morphology in lead V₆ is consistent with ventricular tachycardia. **B**, Some RS complexes are present, RS duration is no longer than 100 msec, and atrioventricular dissociation is difficult to appreciate. The morphologic criteria for ventricular tachycardia are fulfilled because S is notched in V₁ and QR is present in V₆. **C**, Diagnosis is based on morphologic criteria because S is notched in V₁ and V₂ and QS is present in V₆. **Fig. 69.39.** Brugada's syndrome, with ST elevation in V1. The ST elevation is coved (upper, A) or saddle-back (lower, B) and may be transient.

**KEY CONCEPTS**

- Electrical therapy is used for any unstable patient in whom a dysrhythmia is the cause of symptoms—pacing if the heart rate is slow, countershock with sedation if fast.
- Assume that any regular, new-onset, symptomatic, wide-complex tachycardia is VT until proven otherwise.
- Type II second-degree AV block is never a normal variant and implies a conduction block below the AV node. When the conduction ratio is 2:1, assume that type II block exists until proven otherwise and have pacing readily accessible.
- Consider an accessory pathway syndrome in anyone with tachycardia exceeding a rate of 225 to 250 beats/min, regardless of the QRS complex morphology, and avoid nodal blocking agents.
- Look closely for irregularity in tachycardia over 200 beats/min; this and underlying atrial fibrillation can be missed if R-R intervals at fast rates are not carefully tracked.

CHAPTER 69: QUESTIONS & ANSWERS

69.1. What is the primary electrochemical difference between pacemaker and nonpacemaker cells?
A. Lack of a plateau phase 3 in nonpacemaker cells
B. Rapid phase 0 upstroke in nonpacemaker cells after stimulus
C. Slow calcium ion influx during phase 2 for pacemaker cells
D. Slow phase 4 spontaneous depolarization in pacemaker cells
E. Transient membrane repolarization by potassium channel closure during phase 1 for pacemaker cells

Answer: D. The spontaneous return to a depolarization threshold during phase 4 (diastole) characterizes pacemaker cells. Both cell types then exhibit a rapid phase 0 upstroke resulting from sodium ion (Na⁺) influx, brief repolarization resulting from potassium ion (K⁺) efflux (phase 1), plateau phase resulting from balanced calcium ion (Ca²⁺) entry and K⁺ efflux (phase 2), and then repolarization resulting from Ca²⁺ channel closure and K⁺ efflux (phase 3).

69.2. For a reentrant tachydysrhythmia to occur, what three conditions exist?
A. Electrolyte disturbance, ischemia, and altered conduction in an endogenous atrioventricular pathway
B. Electrolyte disturbance, two conduction pathways, with one of the pathways being slower
C. Ischemia, two conduction pathways, with one of the pathways being slower
D. Two conduction pathways, one path being slower, and differing responsiveness
E. Two conduction pathways with equal responsiveness

Answer: D. Remember that a conducting pathway is bidirectional. In a typical scenario, the alpha pathway of the atrioventricular (AV) node is the anterograde conducting limb, and the beta pathway is the retrograde conducting limb. Reentrant dysrhythmias are almost always AV nodal and narrow complexes that start and end abruptly.

69.3. Classic antifibrillatory effects are seen with which class of antidysrhythmic?
A. IA
B. IB
C. IC
D. II
E. III

Answer: E. Class III agents, of which amiodarone is the prototype, prolong the action potential and refractory period duration. Class I agents have variable effects on depolarization rate and repolarization duration.

69.4. The most frequent proarhythmic effects are seen with which class of antidysrhythmic?
A. IA
B. IB
C. IC
D. II
E. III

Answer: C. Class IC agents, such as flecainide, encainide, and propafenone, markedly slow depolarization and conduction and prolong repolarization and action potential duration. Class IB agents generally have the least proarhythmic effect.

69.5. A 49-year-old woman presents with a sudden onset of palpitations and shortness of breath. This has happened once before. She has no past history and takes no medications. Vital signs are temperature, 36.0°C (96.8°F)
oral, blood pressure, 115/69 mm Hg, heart rate 156 beats/min, respiratory rate 24 breaths/min, and oxygen (O₂) saturation, 98%. Her electrocardiogram (ECG) is shown in Fig. 69.28. What is the most appropriate intervention?

A. Adenosine, 6 mg IV
B. Digitalis, 0.25 mg IV
C. Diltiazem, 0.4 mg/kg IV
D. Propranolol, 1 mg IV
E. Synchronized electrical cardioversion after IV sedation with midazolam

Answer: A. Adenosine causes slowing of conduction in the anterograde and retrograde pathways, with no effect on ventricular contractility. It converts a high percentage of narrow-complex tachycardias to sinus rhythm, but with a 25% recurrence rate. Diltiazem would not be unreasonable, but the quoted dose is too high. Calcium channel blockers also exert their effects only on the anterograde pathway, with little direct effect on accessory pathways. Contractility may be diminished. Digitalis use has been largely supplanted by adenosine and class IV agents. Its onset of action after IV use is 1.5 to 2 hours. Cardioversion would not be indicated unless the patient exhibited hemodynamic instability.
CHAPTER 70

Implantable Cardiac Devices

Benjamin Squire | James T. Niemann

PRINCIPLES

Electrical cardiac pacing for the management of bradyarrhythmias was first described in 1952, and permanent transvenous pacing devices were introduced into clinical practice in the early 1960s. The first devices for endocardial defibrillation were implanted in surviving victims of sudden cardiac death in 1980. Implanted electrical devices for the management of cardiac dysrhythmias have changed rapidly over the years, with both increasing complexity and miniaturization. Between 1993 and 2009, 2.9 million new permanent pacemakers were implanted in the United States. Indications for the use of permanent pacemakers in the management of congenital and acquired heart disease has expanded beyond treatment of dysrhythmias to include cardiac resynchronization therapy for heart failure.

A number of large clinical trials comparing implantable cardioverter-defibrillators (ICDs) with antiarrhythmic drugs for the prevention of sudden cardiac death resulting from ventricular dysrhythmias have indicated that ICDs significantly improve survival. Such studies have led to a dramatic increase in ICD implantations, and it is estimated that there are more than 125,000 new ICD implants annually in the United States. The widespread use of these devices assures that emergency clinicians will encounter patients, often with symptoms that may be related to the normal function or malfunction of the pacemaker or ICD.

CLINICAL FEATURES

Guidelines for the implantation of these devices have been developed by a joint task force of the American Heart Association (AHA) and the American College of Cardiology (ACC) and are periodically updated. Similar to categorization of evidence for other recommendations or guidelines, recommendations are categorized as class I, II, or III. Class I includes conditions for which there is general agreement that a device should be implanted. A class II recommendation includes conditions for which these devices are frequently used but for which there is disagreement about their need or benefit. Class III is reserved for conditions for which there is general agreement that a device is not needed.

Class I indications for a permanent pacemaker or ICD are listed in Boxes 70.1 and 70.2. In general, pacing is recommended for patients with symptomatic heart block, symptomatic sinus bradycardia, and atrial fibrillation with a symptomatic bradycardia (low ventricular response rate) in the absence of medications that affect atrioventricular (AV) conduction. Biventricular pacing (cardiac resynchronization therapy) is indicated for systolic heart failure patients with left ventricular ejection fraction under 35% and left bundle branch block.

Pacemaker Terminology

A letter code, initially established in 1974 and revised as technology advances, standardizes nomenclature for pacemakers. Table 70.1 includes an explanation of the five-letter code scheme and the standard abbreviations in each category. The first three code letters are used most commonly. Using this table, one should be able to understand the features of any pacing mode. For example, a VDD (Ventricle, Dual, Dual) pacemaker is capable of pacing only the ventricle, sensing both atrial and ventricular intrinsic depolarization, and responding by dual inhibition of both atrial and ventricular pacing if intrinsic ventricular depolarization occurs; a paced ventricular beat is triggered in response to a sensed intrinsic atrial depolarization. The codes of a permanent pacemaker that are used most frequently and the indications, advantages, and disadvantages of each are listed in Table 70.2. Detailed algorithms for matching a patient with the appropriate pacemaker exist. The majority of permanent pacemakers are dual chamber and most often rate adaptive.

Pacemaker Components

All pacemaker systems have three basic components: the pulse generator, which houses the power source (battery); the electronic circuitry; and the lead system, which connects the pulse generator to the endocardium.

Nearly all implanted pacemakers are lithium powered. Lithium-powered pulse generators function normally for 4 to 10 or more years, depending on the pacemaker features, such as single versus dual chamber, pacing threshold, and rate adaptiveness. This long “battery life” and the fact that the output voltage of the lithium-iodine cell decreases gradually rather than abruptly, as occurred with the early mercury-zinc cell, make sudden pulse generator failure an unlikely cause of pacemaker malfunction.

Permanent pacemakers have endocardial leads that are positioned in contact with the endocardium of the right ventricle and, in the case of a dual-chamber device, the right atrium, with a subclavian or cephalic vein approach used for insertion. Occasionally, an epicardial lead may be implanted during open-heart surgery performed for another indication, such as prosthetic valve insertion or correction of a congenital cardiac defect. Pacemaker leads may be either bipolar or unipolar in configuration. A bipolar endocardial lead has both the negative (distal) and the positive (proximal) electrodes, separated by approximately 1 cm, within the heart. A unipolar lead has the negative electrode in contact with the endocardial surface, and the positive pole is the metallic casing of the pulse generator. Each lead system has potential advantages and disadvantages. The unipolar configuration is not compatible with ICD systems and is prone to oversensing of myopotentials and electromagnetic interference but is of smaller diameter and less susceptible to fracture. The bipolar configuration is compatible with ICD systems but is larger and more prone to lead fractures. Oversensing, however, is rarely a problem. The selection of lead configuration usually depends on patient characteristics, as well as the experience and preference of the operator.

History

The patent should be asked for the pacemaker identification card. The information on the card explains why a pacemaker was placed
and the pacing modality used. If the card is not available, information may be obtained by calling the device manufacturer. If the manufacturer is unknown, calls can be made to the most common manufacturers until the patient is found in one of the registries. All manufacturers provide support including representatives on call to respond to the hospital to interrogate a device.

Most patients with pacemaker malfunction have symptoms reminiscent of those that prompted pacemaker therapy: syncope, near-syncope, orthostatic dizziness, lightheadedness, dyspnea, or palpitations.
The majority of pacemaker complications and most instances of pacemaker malfunction occur within the first few weeks or months of pacemaker implantation. After wound healing, palpation of the pulse generator site should not elicit tenderness. A wound infection or pocket infection typically arises with localized pain. Bacteremia secondary to infection of the pacing catheter, however, may arise only with fever and without other manifestations of the systemic inflammatory response syndrome. Pain in the arm ipsilateral to the site of insertion should suggest acute thrombophlebitis.

Patients who develop the pacemaker syndrome secondary to the loss of AV synchrony may have nonspecific complaints of easy fatigability, generalized weakness, dyspnea, or an uncomfortable fluttering or “pounding” sensation in the neck or abdomen. Syncope or near-syncope may also occur, but these complaints should prompt an evaluation for true pacemaker malfunction. The pacemaker syndrome should be a diagnosis of exclusion.

Physical Examination

A pacemaker infection should be suspected in the presence of fever, even if another potential source of infection can be identified. Extremely low (<60 beats/min) or high (>100 beats/min in the resting patient) pulse rates are suggestive of altered pacing parameters (battery depletion or pacemaker-mediated tachycardia). Hypotension may be present in either instance. Cannon “A” waves on inspection of the jugular venous pulse wave indicate AV asynchrony. Auscultation of lungs may reveal bibasilar rales if congestive heart failure is present.

During pacing, the first heart sound may vary in intensity as a result of AV dissociation (VVI mode), and the second heart sound may be paradoxically split when ventricular pacing occurs (the right ventricle is activated first). A pericardial friction rub may also be heard if the tip of the pacing catheter has perforated the wall of the right ventricle. Perforation, however, usually occurs at the time of pacemaker implantation and is usually recognized at that time. Although the pacing catheter traverses the tricuspid valve, tricuspid regurgitation is rarely heard unless there is myocardial disease such as right ventricular dilation, which is common in the cardiomyopathies. Pedal edema may be present and is important if it is a new symptom or if chronic edema has recently worsened.

Differential Diagnosis

Complications of Implantation

Infection

Pacemaker implantation is a surgical procedure and, like all surgery, carries a risk of infection; the presence of a foreign body enhances this risk. The incidence of infection is small—approximately 2% for wound and subcutaneous pacemaker “pocket” infection and approximately 1% for bacteremia with sepsis. The presence of a foreign body complicates management, and few cases of bacteremia that develop after implantation can be managed with antibiotics alone. In most instances, reimplantation and replacement of the lead system is necessary.

Pain and local inflammation at the site of the pacemaker are the first manifestations of a wound infection, cellulitis, or pocket infection. Approximately 20% to 25% of patients with a local infection have positive blood cultures. Bacteremia may occur in the absence of a focal infection and may arise with the typical manifestations of the systemic inflammatory response syndrome or sepsis. A hematoma of the pacemaker pocket may mimic a wound or pocket infection. Needle aspiration of the pocket should be done only under fluoroscopy, because the needle may cut the insulation surrounding the pulse generator or the portion of the pacemaker lead that lies within the pacemaker pocket.

When a local infection or bacteremia is suspected, blood cultures should be obtained and intravenous antibiotic therapy initiated. *Staphylococcus aureus* and *Staphylococcus epidermidis* are isolated in approximately 60% to 70% of cases. Gram negative infection is rare. Empirical antibiotic therapy should include vancomycin pending culture and sensitivity data. If blood cultures are positive, the pulse generator and pacemaker leads are usually removed, temporary transvenous pacing is performed, and intravenous antibiotic therapy is continued for 4 to 6 weeks. The permanent pacemaker and lead are subsequently reimplemented.

Thrombophlebitis

The incidence of venous obstruction associated with permanent transvenous pacemakers ranges from 30% to 50%, with approximately one-third of patients having complete venous occlusion. Thrombosis of varying degrees can involve the axillary, subclavian, and innominate veins or the superior vena cava (SVC). The site of insertion does not appear to affect the incidence of this complication. Chronic thrombosis of the veins of the upper arm is common and usually asymptomatic owing to extensive venous collateral circulation.

Because of extensive collateralization, approximately 0.5% to 3.5% of patients develop symptoms indicative of acute thrombosis. These patients will commonly have edema, pain, and venous engorgement of the arm ipsilateral to the site of lead insertion. Although rare, SVC syndrome resulting from pacemaker lead-induced thrombosis occurs. The signs and symptoms of lead-induced SVC syndrome are identical to those described in patients with SVC syndrome and malignancy.

Although symptoms might suggest thrombosis, definitive diagnosis of acute thrombosis usually requires duplex sonography of the jugular venous system or contrast-enhanced computed tomography. The symptoms usually respond to systemic anticoagulation therapy followed by long-term anticoagulation. Treatment of these clots is controversial as they are rarely associated with pulmonary embolism. There are no studies comparing treatments for deep vein thrombus (DVT) related to pacemakers. Most commonly, anticoagulation is achieved using low–molecular-weight heparin followed by warfarin for 3 to 6 months.

The “Pacemaker Syndrome”

After pacemaker implantation, a patient may develop new complaints or report a worsening of the symptoms that prompted evaluation and eventual pacemaker therapy. Such complaints often include syncope or near-syncope, orthostatic dizziness, fatigue, exercise intolerance, weakness, lethargy, chest fullness or pain, cough, uncomfortable pulsations in the neck or abdomen, right upper quadrant pain, and other nonspecific symptoms.

These symptoms, termed the pacemaker syndrome, are caused by loss of AV synchrony and by the presence of ventricular atrial conduction. This syndrome is most commonly encountered in the setting of VVI pacing but is also described with the DDI mode. With VVI pacing, the ventricle is electrically stimulated and depolarized, resulting in ventricular systole. If sinus node function is intact, the atria can be depolarized by a sinus impulse and contract when the tricuspid and mitral valves are closed. This contractile asynchrony results in an increase in jugular and pulmonary venous pressures and may produce symptoms of congestive heart failure.

Atrial distention can result in reflex vasodepressor effects mediated by the central nervous system. Elevated levels of B-type natriuretic peptide (BNP) and diuresis are considered markers for the syndrome in its more severe form. If the contribution of atrial
contraction to late diastolic ventricular filling is important in maintaining an adequate cardiac output, basal and orthostatic hypotension may occur. DDI pacing in a patient with AV block may result in this syndrome if the sinus node discharge rate exceeds the programmed rate of the pacemaker.

Approximately 20% of patients report symptoms suggesting the pacemaker syndrome after pacemaker insertion. In most instances, symptoms are mild and patients adapt to them. In approximately one-third of these patients, symptoms are severe. Treatment usually requires replacing a VVI pacemaker with a dual-chamber pacemaker or lowering the pacing rate of the VVI unit. If symptoms occur in a patient paced in the DDI mode, optimizing the timing of atrial and ventricular pacing is usually required. Patients appear to prefer dual-chamber pacing to the VVI modality.17

Pacemaker Malfunction

The term pacemaker malfunction refers specifically to problems with the circuitry or power source of the pulse generator, the pacemaker lead (most commonly displacement or fracture), or the interface between the pacing electrode and the myocardium (pacing or sensing threshold). In addition, environmental factors, such as extracardiac or extracorporeal electrical signals, may interfere with normal pacemaker function.18,19 With use of the standard electrocardiogram (ECG), pacemaker malfunction can be separated into three broad categories: (1) failure to capture (no pacemaker spikes or spikes not followed by an atrial or ventricular complex), (2) inappropriate sensing (oversensing or undersensing spikes occur prematurely or do not occur even though the programmed interval is exceeded), or (3) inappropriate pacemaker rate. Symptomatic pacemaker malfunction after implantation occurs in less than 5% of patients and is rarely immediately life-threatening. Malfunction is most commonly a result of inappropriate sensing, followed by failure to capture. Typical presentations and causes of pacemaker malfunction are listed in Box 70.3.

In the context of suspected pacemaker malfunction, knowledge of the pacing modalities (see Table 70.1) and what is normal for a given pacing modality are critical when the ECG is reviewed. Fortunately, patients are provided with important identifying information, usually in the form of a wallet card, after pacemaker implantation. The most important information is provided in the five-letter code. Many patients will carry a card with the specifics of their pacemaker. If that is not available and the pacer type is not described in the medical records, a standard posteroanterior chest radiograph can provide clues based on number and placement of leads. A single lead in the apex of the right ventricle indicates a VVI pacemaker. With VVI pacing, only one stimulus artifact or spike is seen with each stimulated ventricular depolarization (Fig. 70.1). If sinus node activity is present, the paced QRS complex is dissociated from the intrinsic P waves. If separate leads are identified in the right atrium and right ventricle, the pacing modality is most often DDD or DVI, and paced P waves and QRS complexes (two spikes for each QRS complex) are seen (Fig. 70.2). Although DDD and DVI units are capable of pacing both the right atrium and the right ventricle, only one spike may be seen (Fig. 70.3). Failure to identify two spikes with a DDD or DVI unit can represent normal pacemaker function.

A magnet placed externally over the pulse generator is occasionally used in the assessment of pacemaker function. Magnet application causes closure of a reed switch, turning off sensing function, thus converting the pacemaker to fixed-rate pacing. The technique is most commonly used when the patient’s intrinsic heart rate exceeds the pacemaker’s set rate and pacemaker function is inhibited. Magnet application then allows pacing to occur, despite the patient’s native cardiac activity, and pacing rate and the presence of capture can be determined. Magnets are made by each manufacturer, but any cardiac pacemaker magnet will typically activate the reed switch in any device.

Failure to Capture

Failure to capture may range from the complete absence of pacemaker spikes to spikes not followed by a stimulus-induced

---

**Fig. 70.1.** Normal VVI pacemaker (rhythm strip). This rhythm strip was recorded in a patient with a VVI pacemaker implanted for the treatment of symptomatic complete heart block. The pacing rate is approximately 75 beats/min (determined by measuring the time between consecutive pacemaker spikes). Each pacemaker spike is followed by a paced QRS complex. The third QRS from the left has a slightly different morphology than the paced QRS complexes. It is an intrinsic QRS complex that is sensed by the pacemaker, and a paced beat does not occur again until the programmed rate of the pacemaker is exceeded. The time interval between the spontaneous QRS and the next paced beat is approximately the same as the interval between consecutive pacemaker spikes. This sequence is subsequently repeated twice on this strip.
changes over a period of months to a year before complete depletion. Usually the first sign of voltage depletion is a decrease in the programmed pacing rate. This change is gradual and should be detected during the regular follow-up evaluations that pacemaker patients receive. When voltage output falls to a critical level, complex (Fig. 70.4). A complete absence of pacemaker spikes may result from battery depletion, fracture of the pacemaker lead, or disconnection of the lead from the pulse generator unit.

Current lithium-iodine batteries are not subject to sudden power failure, and they display typical end-of-life functional changes over a period of months to a year before complete depletion. Usually the first sign of voltage depletion is a decrease in the programmed pacing rate. This change is gradual and should be detected during the regular follow-up evaluations that pacemaker patients receive. When voltage output falls to a critical level,
stimulus strength falls below the required threshold, and failure to capture or intermittent failure to capture may be observed late in battery life. As a result, urgent or emergent battery replacement is rare.

Failure to capture, which may be complete or intermittent, is most commonly a lead problem. Lead displacement is the most common cause and is most likely to occur within the first month of pacemaker insertion. The chest radiograph may demonstrate the tip of the pacing catheter displaced from the right ventricular apex. The catheter tip is commonly found in the pulmonary outflow tract, where it may have intermittent contact with endocardium, resulting in intermittent failure to pace and sense. The atrial leads of dual-chamber devices are commonly displaced into the body of the right atrium, resulting in loss of contact between the pacing lead and the atrial endocardium.

Lead fracture, which is uncommon with the current polyurethane lead coating, produces an insulation break, resulting in failure to capture as a result of current leakage. It can be detected as a change in pacing threshold during pacemaker interrogation. Lead fractures occur at predictable locations, usually at the site of attachment to the pulse generator or at abrupt angulations that serve as stress points. Inadequate contact of the lead with the pulse generator can mimic a lead fracture. Occasionally, when a lead fracture is complete or nearly complete, a break in the catheter or its insulation can be detected on an over-penetrated posteroanterior chest radiograph. Loss of lead-pulse generator contact can be detected on the chest radiograph with close inspection of the pulse generator.

Exit block (the failure of an adequate stimulus to depolarize the paced chamber) can also result in failure to pace. Exit block should be considered when the preprogrammed pacing stimulus output fails to result in capture in the presence of a normally functioning pulse generator and an intact lead system. Most commonly this problem is a result of changes in the endocardium in contact with the pacing system. Causes include ischemia or infarction of the endocardium in contact with the electrodes, systemic hyperkalemia, and the use of class III antiarrhythmic drugs (such as, amiodarone), which affect ventricular depolarization. Although other drugs alter pacemaker threshold, the effect is small and is rarely clinically important.

Inappropriate Sensing

For a pacemaker to function in a noncompetitive mode, it must be capable of sensing the intrinsic or “native” electrical activity of the heart. The electrical activity that is sensed is determined by the pacing modality (see Table 70.1). Sensing parameters are determined at the time of pacemaker insertion on the basis of the signal size of the intracardiac ECG and can be changed or fine-tuned externally at a later time if needed.

Undersensing

Failure to sense may be complete or intermittent. It may result from a change in the sensing parameters selected at the time of insertion. This is most commonly encountered after acute right ventricular infarction or during the progressive fibrosis that accompanies many cardiomyopathies, causing intracardiac signals to decrease in amplitude. Lead displacement, fracture, and poor contact with the endocardium may also cause undersensing.

Undersensing is typically recognized electrocardiographically as the appearance of pacemaker spikes occurring earlier than the programmed rate. The spike may or may not be followed by a paced complex, depending on when it occurs during the cardiac refractory period (Fig. 70.5). Failure of a stimulus spike to produce a complex when it occurs during the atrial or ventricular refractory period should not be interpreted as failure to pace.

Oversensing

In rare instances, the pacemaker may detect electrical activity that is not of cardiac origin. The result may be intermittent, irregular
Inappropriate Pacemaker Rate

A pacing rate below the programmed rate is a typical finding in pulse generator depletion and does not occur abruptly with lithium-iodine batteries. An extreme increase in pacing rate, the so-called “runaway pacemaker,” is rarely, if ever, encountered with current pacemaker technology and circuitry in which upper rate limits are set (typically 140 beats/min). An “endless loop” tachycardia may develop during dual-chamber pacing when ventricular atrial conduction occurs, and the resulting retrograde atrial depolarization results in a stimulated or paced ventricular depolarization. If atrial flutter develops during dual-chamber pacing, flutter waves may be sensed and tracked, resulting in a rapid, paced ventricular rate. In both instances, the ventricular rate does not exceed its set upper limit. Patients with such rhythms may complain only of palpitations or symptoms of hemodynamic compromise. When such rhythms are detected, magnet application converts the pacemaker to a fixed rate and terminates the tachycardia.

The modern pacemaker has two basic functions: (1) to stimulate the heart electrically and (2) to sense intrinsic cardiac electrical activity. Additional functions are available and are noted in the pacemaker code system (see Table 70.1, letters 4 and 5). The pacemaker delivers an electrical stimulus to either the atrium or the ventricle if it does not recognize (sense) any intrinsic electrical activity from that chamber after a selected time interval. This interval is usually programmed at the time of implantation and can be changed noninvasively at a later time, if necessary, with use of a programming and an “interrogating” device provided by the pacemaker manufacturer. If the pacemaker recognizes or senses an intrinsic atrial depolarization (P wave) or ventricular depolarization (QRS complex), it inhibits or resets its output to prevent competition with the underlying intrinsic rhythm. The stimulus intensity and sensing threshold (amplitude of electrical activity that is detected as being intrinsic) are typically set at the time of implantation but can also be reprogrammed later.

The two basic functions of a pacemaker can be easily recognized and confirmed on a standard 12-lead ECG or rhythm strip. The normal function of a single-chamber VVI pacemaker is most easily recognized (see Fig. 70.1). After a programmed interval is surpassed during which intrinsic ventricular activity does not occur, a pacer “spike” or stimulus artifact appears. The pacer spike is a narrow deflection that is usually less than 5 mm in amplitude with a bipolar lead configuration and usually 20 mm or more in amplitude with a unipolar lead. A wide QRS complex appears immediately after the stimulus artifact. Depolarization begins in the right ventricular apex, and the spread of excitation does not follow normal conduction pathways. Characteristically, a left bundle branch block conduction pattern is seen. A right bundle branch pattern is abnormal and may represent lead displacement through a patent foramen ovale, placement of the lead in the coronary sinus, septal perforation, or may be seen with safe right ventricular apical position. In VVI pacing the paced QRS complexes are independent of intrinsic atrial depolarization if present (AV dissociation).

The recognition of normal dual-chamber pacing is more complex owing to the interactive sensing and pacing of the right atrium and ventricle (see Fig. 70.2). Dual-chamber devices are typically used in patients with non-fibrillating atria coupled with intact AV conduction. A normal-appearing QRS complex may follow an intrinsic P wave as a result of normal sinoatrial node discharge if the intrinsic atrial depolarization is conducted to the ventricles. The intrinsic P wave and QRS complex inhibit the atrial and ventricular circuitry. A normal QRS complex follows a paced P wave if the paced atrial beat is conducted through the AV node and the programmed AV delay period is not exceeded. If it is not conducted to the ventricles (AV delay period exceeded), the pacemaker stimulates the ventricle, resulting in a paced P wave and a wide, paced QRS complex with left bundle branch block configuration.

Recognition of the interactivity of the paced chambers is important. A paced P wave may be mistaken for failure to sense...
or pace, and malfunction may be diagnosed when it is not present (pseudomalfuction). In addition, if the programmed rate of the pacemaker approximates the patient’s intrinsic heart rate, fusion of paced and native beats may occur and represents another common type of pseudomalfuction (Fig. 70.7).

**MANAGEMENT**

**Advanced Cardiac Life Support Interventions**

Electrical defibrillation at recommended shock strengths (200, 300, and 360 J) can be safely performed in the patient with a pacemaker. If the sternal defibrillation pad is placed adjacent to the sternum, it is at a safe distance (>10 cm) from the pulse generator. Alternatively, defibrillation electrodes can be placed in an anteroposterior configuration. All pacemakers should be interrogated after successful resuscitation, as well as placement. A chest radiograph should also be obtained to ensure that the pacing catheter was not displaced during chest compression.

Immediate return of pacing (capture) may not occur after defibrillation; this is commonly the result of global myocardial ischemia and increased pacing threshold and is not an indication of pacemaker malfunction. Temporary transvenous pacing may be needed if the pacemaker cannot be reprogrammed or normal pacing does not resume spontaneously. Transcutaneous pacing can also be safely used because the anterior and posterior pacing electrodes, if properly positioned, are distant from the pulse generator. Attempting temporary transvenous pacing is usually not necessary and is unlikely to be successful without fluoroscopic guidance and may also dislodge the permanent catheter.

Chronic venous thrombosis, which is common and most often asymptomatic after pacemaker insertion, may preclude temporary catheter insertion through the neck veins. Insertion through the femoral vein is also difficult because the permanently implanted catheter may prevent entry into the right ventricle.

**DISPOSITION**

As a result of the current design of modern pacemakers and the frequent follow-up evaluation of patients with pacemakers, life-threatening emergencies resulting from pacemaker malfunction requiring emergent intervention are rare. Most instances of malfunction are subtle and difficult to recognize without interrogation of the pacemaker with manufacturer-specific devices by an individual trained in pacer interrogation. In all instances of suspected pacemaker malfunction, the patient’s cardiologist should be consulted.

**Implantable Cardioverter-Defibrillators**

**Principles**

The ICD was first used clinically in 1980. Technical refinements to this modality for treating ventricular dysrhythmias have progressed even more rapidly than refinements to the less complex standard pacemaker. A surge in the use of ICDs is reflective of improved survival with ICDs versus antiarrhythmic therapy in patients at risk for sudden cardiac death. Generally accepted indications for ICD implantation are noted in Box 70.2. Many patients still require drug therapy after ICD implantation to suppress ventricular dysrhythmias, minimize the frequency of ICD shocks, improve patients’ tolerance, and decrease energy use, which prolongs ICD life.

**Clinical Features**

**Terminology and Components**

The majority of ICDs are now placed percutaneously in a manner similar to that of the standard pacemaker. A transvenous electrode system has largely replaced epicardial lead placement, which required thoracotomy. An epicardial defibrillation lead may occasionally be placed during coronary artery bypass surgery or in a few patients who cannot be defibrillated with use of existing transvenous electrode systems.

The typical modern ICD consists of components similar to those in the standard permanent pacemaker, namely, a power source, electronic circuitry, and lead system. In addition, the standard ICD has a high-voltage capacitor and complex microprocessor memory. The power source is lithium chemistry based with a battery life of 5 to 10 years. The longevity is largely determined by the frequency of shocks. All ICDs are also ventricular pacemakers. The right ventricular lead is used for sensing and pacing, and shocks are typically delivered between a coil in the right ventricular lead and the pulse generator. If dual-chamber pacing is required, a second lead is placed in contact with the endocardium of the right atrium. A biphasic waveform is currently the preferred waveform for internal defibrillation. The biphasic waveform is more effective at lower energies than earlier monophasic waveforms and allows a smaller capacitor to be used, thereby reducing the size and increasing the comfort of the ICD unit.

The diagnostic and treatment functions of the ICD are determined at the time of implantation. In most instances, the cardioversion and defibrillation thresholds are determined at the time
of ICD insertion by inducing ventricular tachycardia (VT) and ventricular fibrillation (VF) and adjusting the shock strength at a level above the minimum required to terminate the induced rhythm. Optimally, the required shock strength for defibrillation is less than half the maximum output (approximately 30 J) of the device. VT is typically managed with use of either low-energy shocks or antitachycardia pacing that interrupts the VT reentrant circuit. Antitachycardia pacing is less likely to have proarrhythmic effects and requires less energy, thereby extending battery life. In the setting of VF, ICDs are capable of delivering up to five additional shocks if the first shock fails.

DIFFERENTIAL DIAGNOSIS

Complications of Implantation

Complications of ICD implantation are nearly identical in type and frequency to those of permanent pacemaker implantation and management as well.

Malfunction

Patients with ICD malfunction usually come to the emergency department (ED) with a limited number of specific symptoms (Box 70.4).

In contrast to patients with a permanent pacemaker, ICD patients are usually aware of when the ICD delivers a discharge or shock. The most common complaint of ICD patients is the occurrence of frequent shocks. An increasing shock rate may be appropriate and not indicative of ICD malfunction if the patient is experiencing an increase in the frequency of VT or VF episodes. An increase in the frequency of episodes may occur in the setting of hypokalemia, hypomagnesemia, ischemia (with or without infarction) related to underlying coronary artery disease, or the proarrhythmic effect of drugs administered to decrease the frequency of ventricular tachyarrhythmias. Many ICD patients, particularly those with newly implanted devices, report that their device has discharged, but subsequent device interrogation reveals that no discharge occurred.

An increase in the shock frequency is a manifestation of ICD sensing malfunction if (1) a supraventricular tachyarrhythmia is inappropriately sensed as VT; (2) shocks are delivered for nonsustained VT, or (3) intracardiac T waves detected by the ICD system are sensed as QRS complexes and the ICD interprets this as an increased heart rate. Temporary ICD deactivation with magnet application may be necessary if oversensing is the problem. Syncope, near-syncope, dizziness, or lightheadedness in the patient with an ICD may indicate undersensing of sustained VT or inappropriately low shock strength to terminate the rhythm. An approach to the evaluation of ICD malfunction is shown in Fig. 70.8.

DIAGNOSTIC TESTING

Diagnostic testing depends on presenting symptoms. As with pacemakers, chest radiograph can identify lead placement. ECG is indicated to evaluate for arrhythmias. Patients who present with history of more than one ICD shock should have the ICD interrogated while in the ED.

MANAGEMENT

Advanced Cardiac Life Support Interventions

An ICD does not prevent sudden death in all patients at risk, and a patient with an ICD may arrive in cardiac arrest (2% annual incidence in patients with implanted devices). Cardiac arrest is not necessarily an indication of ICD malfunction. Appropriate repeated shocks may have been delivered but were ineffective. Alternatively, the ICD may not have sensed VF or the ventricular ectopic activity that typically precedes VF. Resuscitation efforts in the patient with an ICD should be undertaken in accordance with current recommendations. Transthoracic defibrillation can be performed in the standard manner with a monophasic or biphasic

---

**BOX 70.4**

**Causes of Implantable Cardioverter-Defibrillator Malfunction**

Increase or abrupt change in shock frequency
- Increased frequency of VF or VT (consider ischemia, electrolyte disorder, or drug effect)
- Displacement or break in ventricular lead
- Recurrent nonsustained VT
- Sensing and shock of supraventricular tachyarrhythmias
- Oversensing of T waves
- Sensing noncardiac signals
  - Syncope, near-syncope, dizziness
- Recurrent VT with low shock strength (lead problem, change in defibrillation threshold)
- Hemodynamically significant supraventricular tachyarrhythmias
- Inadequate backup pacing for bradyarrhythmias (spontaneous or drug induced)
- Cardiac arrest
- Assume malfunction, but probably caused by VF that failed to respond to programmed shock parameters

VF, Ventricular fibrillation; VT, ventricular tachycardia.

---

defibrillator if VF is the arrest rhythm. The sternal electrode or paddle should be placed in a parasternal location approximately 10 cm from the ICD subcutaneous pouch if the device has been implanted in the right deltopectoral area. If it has been implanted in the left deltopectoral region, this recommended safety distance is usually exceeded.

ICD discharge during manual chest compressions poses no risk to providers, although the rescuer may feel a weak shock. Although generally not indicated, the device can be deactivated with magnet application during resuscitation. Deactivation is probably more important in the immediate post-resuscitation period. Ventricular dysrhythmias are common at this time due to prolonged global myocardial ischemia during the arrest period, reperfusion, and the hyperadrenergic state, which is worsened by the use of intravenous epinephrine during resuscitation. ICD malfunction should be assumed, and these post-resuscitation rhythms treated with standard pharmacologic agents (lidocaine and amiodarone). Although class I antidysrhythmic agents may raise the defibrillation threshold of the ICD, their impact on the defibrillation threshold during transthoracic countershock, due to the high energy, is clinically inconsequential.

**DISPOSITION**

As a result of the difficulty in documenting or excluding ICD function or malfunction in the patient with transient symptoms, the device should be interrogated to guide further evaluation and therapy. In cases in which the patient reports a single ICD shock, an assessment for acute cardiac ischemia, worsening of chronic congestive heart failure, symptoms of new-onset heart failure, and electrolyte abnormalities should be performed. In the absence of a change in clinical status, such patients can be discharged in consultation with the managing or consulting cardiologist after timely follow-up is ensured. For patients reporting multiple shocks, interrogation is essential, because in many of these cases the defibrillator has not discharged and the patient is experiencing hiccoughs, diaphragmatic twitching, or other nonelectrical phenomena. In such cases, discharge home is the rule. When multiple defibrillator discharges are confirmed by interrogation, emergent consultation is required along with admission to a monitored setting for extended telemetric observation. If frequent ventricular ectopy is noted, intravenous amiodarone is indicated. ICD interrogation allows assessment of ICD function and preceding dysrhythmia episodes. Based on the findings, reprogramming may be required. Similar to a pacemaker, a magnet can be placed over the ICD to inactivate the defibrillator. This should be done only if the emergency clinician is confident that the ICD is delivering inappropriate shocks, such as a supraventricular tachycardia.

**BIVENTRICULAR PACING**

**PRINCIPLES**

Biventricular pacing, also known as cardiac resynchronization therapy, is a therapy for patients with left-sided heart failure and ventricular dyssynchrony. Indications for biventricular pacing have expanded to include patients with New York Heart Association (NYHA) class II, III or IV heart failure, left ventricular dysfunction, and left bundle branch block, or patients with AV block and ventricular systolic dysfunction with NYHA class I, II, or III heart failure.

**CLINICAL FEATURES**

Left bundle branch block causes an altered sequence of depolarization of the left ventricle such that the interventricular septum contracts before the left ventricular free wall, leading to inefficient mechanical pumping. Biventricular pacing “resynchronizes” the ventricles by simultaneously pacing the left and right ventricles, eliminating the delay in left ventricular free wall contraction and improving systolic function. Right atrial and right ventricular leads are positioned as for conventional atrial and univentricular pacing. The left ventricular lead is positioned in a left ventricular epicardial location via the coronary sinus and veins, preferably in a posterolateral or lateral location. The QRS duration of paced ventricular complexes is often but not always less than the QRS duration measured before resynchronization therapy. Cardiac resynchronization therapy has not been shown to be beneficial in heart failure with narrow QRS.

**DIFFERENTIAL DIAGNOSIS**

The complications and malfunctions inherent with conventional cardiac pacing are also observed with biventricular pacing. In addition, biventricular pacing has unique complications related to placement of the left ventricular pacing lead through the coronary sinus. In large clinical trials, coronary sinus dissection occurred in 0.3% to 4.0% of patients and coronary sinus perforation in 0.8% to 2.0% of patients. Cardiac tamponade caused by perforation of the coronary venous system is seen in less than 1% of patients. Dislodgement of the left ventricular electrode with resultant loss of pacing occurs as an early complication in approximately 10% of patients. Patients with malfunction of a biventricular pacing system frequently report palpitations or acute decompensation of chronic heart failure.

**DIAGNOSTIC TESTING**

Biventricular pacing can usually be recognized on the standard ECG (Fig. 70.9). Two stimulus artifacts or “spikes” may be seen preceding a paced QRS complex. With biventricular pacing, a predominantly negative QRS complex is seen in lead I, in contrast to the typical upright complex seen with right ventricular pacing (see Fig. 70.2). A predominantly positive QRS complex is seen in lead V1 with biventricular pacing.

**MANAGEMENT**

Patients with biventricular pacemakers have advanced heart failure and may be treated using all current heart failure treatments (see Chapter 71). As with standard pacemakers, transvenous pacing is rarely needed and may be difficult due to preexisting leads blocking passage of the transvenous pacing wire. Cardiac tamponade due to pacemaker placement is treated using usual technique. Treatment of lead misplacement or dislodgement requires cardiology consultation.

**DISPOSITION**

Disposition of patients with biventricular pacemakers will depend on presenting symptoms and or complications.

**CARDIAC ASSIST DEVICES**

**PRINCIPLES**

Mechanical ventricular assistance devices have been used as a “bridge” to transplantation since the 1960s. Newer devices, such as the Jarvik 2000 and HeartMate II, are continuous flow pumps that are portable and powered with long lasting, wearable battery packs allowing patients to live in their community. With advancing technology, infectious complications and postoperative mortality have decreased, significantly with 2 year survival in over half
of patients. The greatest mortality is noted within the first 30 days after implantation and during hospitalization. These mechanical assist devices may be used as a bridge to cardiac transplantation or as “destination” therapy in patients who do not qualify for cardiac transplantation. Three types of implanted heart assist devices now exist. These include the left ventricular assist device (LVAD), the biventricular assist device (BiVAD) and the total artificial heart (TAH).

Mechanical options for patients with biventricular heart failure include the BiVAD and the TAH. The BiVAD is similar to the LVAD, but it consists of two pumps—one assisting the right ventricle, one assisting the left ventricle. The failing heart is left in place while the pumps are attached to it. The mechanism, as well as complications and precautions for the BiVAD are similar to those for the LVAD.

**CLINICAL FEATURES**

The LVAD supports the patient’s cardiac output via a mechanical pump that draws blood from an inflow cannula in the left ventricle and pumps it into the ascending aorta via an outflow cannula. The pump at the left apex is connected via a driveline exiting the patient at the epigastrium to the external controller box. The controller box and batteries are worn by the patient on a belt and shoulder harness, allowing freedom of movement. The controller displays battery life and alarms. Patients with LVADs require lifelong anticoagulation to prevent the graft from clotting. Most patients also have a pacemaker or automatic implanted cardioverter-defibrillator (AICD) placed.

The most common LVADs produce a non-pulsatile flow, therefore patients are essentially pulseless making traditional hemodynamic vital sign interpretation impossible. Adequate perfusion can be assessed by evaluating mental status and alertness, oxygenation, and renal function. Blood pressure may be measured using a manual cuff with a Doppler probe over the radial or brachial artery. The cuff pressure is reduced until a constant sound is heard. The pressure at this point represents the mean arterial pressure. Blood pressure can also be measured invasively using an arterial catheter.

Assessing the LVAD for device malfunction can be challenging, but assistance is available by calling the patient’s LVAD coordina-tor by phone, as well as enlisting the help of the patient’s family members who receive extensive training when the device is implanted. The screen on the control panel can help determine if the problem may be due to battery level, flow, or other malfunction. Listening to the epicardium should reveal a continuous noise if the pump is operating.

**DIFFERENTIAL DIAGNOSIS**

Like any other patient with indwelling catheters, the driveline can become a conduit for infection and patients with LVADs are prone to infections that may be localized around the LVAD device, as well as systemic including bacteremia. These infections are treated with broad-spectrum antibiotics, including methicillin-resistant *Staphylococcus aureus* (MRSA) coverage with device removal rarely necessary.

Most LVAD patients are anticoagulated and are at increased risk for bleeding. This most frequently presents as intracranial or gastrointestinal hemorrhage. In addition to pharmacologic anticoagulation, patients with LVADs can develop acquired von Willebrand’s factor (vWF) platelet dysfunction. Reversal of anticoagulation should be approached with caution due to risk of graft failure due to obstructing thrombus, and patients who are inadequately anticoagulated are at risk for pump failure due to thrombus. A patient with hemodynamic collapse due to clot on inflow or outflow cannulas can be treated with intravenous heparin or in extreme cases, thrombolyis.

Patients with an LVAD experiencing signs of shock or poor perfusion may be due to right ventricular failure, because the device does not support the right ventricle. This can be evaluated with a bedside echocardiogram showing a small right ventricle with poor contraction. In these cases, preload augmentation with titrated fluid boluses may improve hemodynamics. Inotropes such as dopamine, dobutamine, or a combination of these drugs have also proven beneficial in these situations.

Dysrhythmias are frequent with LVAD patients. Because the pump can maintain forward flow despite dysrhythmias, the patient may remain awake and conscious despite persistent VF. Most patients have an AICD place, which should respond to tachydysrhythmias. If there is no AICD or the AICD is not functioning, LVAD patients may be cardioverted using standard...

*BP*, Blood pressure.

In contrast to the BiVAD, with the TAH, the failing heart is removed and the TAH implanted. The currently available TAH (SynCardia) produces pulsatile flow. Because the native heart has been removed, patients with a TAH have no cardiac electrical activity (asystole); therefore defibrillation and pacing are never indicated. Chest compressions are not effective with the TAH and could be harmful due to traumatic disruption of the heart or drive lines. Epinephrine and vasopressin are generally not recommended for TAH patients, because there is no native heart to respond.

**DIAGNOSTIC TESTING**

ECG is useful in LVAD patients to identify arrhythmias. Ultrasound or echocardiogram may be used for LVAD patients to confirm blood flow. Electrocardiography and echocardiography are not useful in patients with the TAH, because there is no native heart and no electrical activity.

**MANAGEMENT**

Chest compressions risk dislodging the device, resulting in massive hemorrhage, although a recent case series of eight patients with LVAD who received chest compressions showed no cannula dislodgements with four patients surviving the initial arrest. Prior to considering chest compressions, multiple methods should be used to confirm absence of circulation, and attempts should be made to correct mechanical pump malfunction. In some devices, the hand pump can be used to provide backup circulation, and early transition to cardiopulmonary bypass should be considered (Table 70.3).

**KEY CONCEPTS**

- Pacemaker malfunction soon after implantation (within 6 to 8 weeks) is usually a result of a lead problem, such as a lead displacement, or a pacemaker programming failure, such as a pacing rate too slow for the patient’s needs.
- Pacemaker malfunction arises in a limited number of ways: failure to pace, oversensing, undersensing, and pacing at an inappropriate rate (too fast or too slow).
- With lithium-iodine batteries, abrupt failure is an unlikely cause of pacemaker malfunction.
- If a patient with a pacemaker has a fever of unclear cause, pacemaker lead infection and endocarditis should be considered.
- Because paced ventricular complexes are conducted with a left bundle branch block pattern, a paced rhythm obscures the electrocardiographic diagnosis of acute myocardial infarction. A right bundle branch pattern is abnormal and suggests lead displacement.
- Magnet application does not turn off a pacemaker, it turns off the sensing or inhibition function. Fixed-rate pacing that is independent of or in competition with the underlying native rhythm will ensue. Removal of the magnet restores the inhibitory activity of the pacemaker and returns it to demand pacing mode.
- Defibrillation is safe in patients with a pacemaker or implantable cardioverter-defibrillator (ICD). Paddles should be placed at least 10 cm from the subcutaneous implant site of the device. Alternatively, anteroposterior defibrillation with adhesive defibrillation electrodes can be performed. There are no reports of injury to rescuers from ICD discharges during manual chest compressions.
- Most left ventricular assist device (LVADs) do not produce pulsatile flow; therefore, these patients will not have a palpable pulse. Because chest compressions may be harmful, multiple methods should be used to confirm absence of circulation and attempts should be made to correct mechanical pump malfunction.
- Patients with a total artificial heart (TAH) have no native heart and no cardiac electrical activity. Electrocardiogram (ECG) for the TAH will read asystole. Defibrillation and pacing will not be effective. Chest compressions will not be effective and may be harmful.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
unipolar systems, the proximal lead is enclosed in the pulse generator and is likely to oversense myopotentials and are also ICD compatible. In bipolar systems, the proximal (positive) and distal (negative) leads in close proximity to each other on the surface of the endocardium. Bipolar leads are more fracture prone but less likely to oversense myopotentials and are also ICD compatible. In unipolar systems, the proximal lead is enclosed in the pulse generator. Typical lithium battery life is 4 to 10 years. Unipolar lead amplitude is approximately four times longer than typical bipolar spikes (20 mm vs. 5 mm). Lead placement should not be in the outflow tract.

70.3. A 72-year-old man presents with dyspnea. He has a history of symptomatic bradycardia that required pacemaker placement and a history of hypertension and peripheral vascular disease. In the course of your evaluation, an electrocardiogram (ECG) is obtained showing a ventricular-paced rhythm with a right bundle branch morphology, rate 72. Vital signs are normal. This likely indicates which of the following?
A. A nonfunctioning atrioventricular (AV) sequential system
B. A ventricular demand pacemaker
C. Electrolyte disturbance
D. Lead displacement
E. Right ventricular apex depolarization by a unipolar endocardial lead

Answer: D. The typical depolarization begins in the right ventricular apex, and a left bundle branch pattern is the norm. The presence of a right bundle branch block (RBBB) pattern should raise suspicion of lead displacement. Electrolyte disturbance does not typically cause a morphology change.

70.4. A 60-year-old man presents with swelling and tenderness around his left subclavian pacemaker. It was implanted 2 years previously for heart block. It was last interrogated 8 weeks prior by his cardiologist, with good function documented. Physical examination is unremarkable except for mild tenderness with minimal swelling and erythema at the pulse generation site. Vital signs are unremarkable.
Which of the following interventions should be performed next?
A. A course of oral antibiotics with *Staphylococcus aureus* coverage should be initiated.
B. Blood cultures should be sent.
C. Local aspiration should be considered to rule out hematoma.
D. Serial examinations would be acceptable management.

**Answer:** B. The incidence of wound/pocket infection is 1% or 2%. With infection, however, the incidence of bacteremia is 20% to 25%. Local signs may be minimal. If pacemaker site infection is suspected, blood cultures, admission for intravenous (IV) antibiotics, and cardiology consultation with the potential need for pacemaker explantation should be undertaken.

**70.5.** What is the incidence of venous obstruction after permanent transvenous pacemaker placement?
A. <15%  
B. 15% to 30%  
C. 30% to 50%  
D. 50% to 70%

**Answer:** C. This may be partial or complete and involve the axillary, subclavian, innominate veins, or the superior vena cava (SVC). Because of collateralization, only approximately 4% of patients develop symptoms consistent with acute thrombosis. Thrombolytic therapy is most useful within the first 2 weeks.

**70.6.** Which of the following statements best describes risk of pacemaker syndrome in patients receiving a permanent pacemaker?
A. It is most common with VVI pacemakers.
B. It is not seen with dual-chamber pacing systems.
C. It occurs in less than 5% of patients after pacemaker placement.
D. It occurs in the setting of preexisting congestive heart failure (CHF).

**Answer:** A. Pacemaker syndrome occurs in approximately 20% of pacemaker recipients. It is due to poor atrioventricular (AV) synchrony occurring when the ventricle is paced, but an intact sinus node stimulates the atria to fire against closed tricuspid and mitral valves. CHF symptoms and elevated B-type natriuretic peptide (BNP) may be seen. It occurs less commonly with DDI systems, but when it does occur, it may require reprogramming for better AV synchrony. It is most common after VVI placement.

**70.7.** A 72-year-old woman presents in cardiac arrest. Her history is remarkable for automatic implanted cardiac defibrillator (AICD) implantation 6 months ago for recurrent ventricular tachycardia (VT). No other history is available. The rhythm is ventricular fibrillation (VF). Which of the following is next best steps?
A. Her cardiac arrest is indicative of implanted cardiac defibrillator (ICD) failure.
B. ICD should not be inactivated because of the high incidence of post resuscitation ventricular dysrhythmias.
C. Rescuers should be warned of potential painful shocks while performing cardiopulmonary resuscitation (CPR).
D. Transthoracic defibrillation may be performed in the standard manner for VF.

**Answer:** D. ICD does not prevent sudden death, as evidenced by the 2% annual incidence. Cardiac arrest is not an indication of ICD failure, because shocks may have been ineffective or there may have been a failure to sense. Transthoracic defibrillation may be done in the standard manner, but with attempts to keep the paddle 10 cm from the generator, very mild shocks may be felt by the person performing CPR, but these are not painful or dangerous. Immediate deactivation is not a priority but should be considered in the post resuscitation period, when the ICD may not function well.
Heart failure is a debilitating cardiac condition characterized by dyspnea, poor exercise tolerance, and chronic fatigue, along with high morbidity and mortality. Heart failure may be defined as the pathophysiologic state in which the heart is incapable of pumping a sufficient supply of blood to meet the metabolic requirements of the body, or requires elevated ventricular filling pressures to accomplish this goal. The caveat about high filling pressures acknowledges that a failing heart may continue to maintain systemic perfusion via the compensatory Frank-Starling mechanism, resulting in the maintenance of normal stroke volume (SV) despite reduced ejection fraction (EF). Conversely, low filling pressure with hypoperfusion indicates a pump-priming problem distinct from cardiac disease.

Heart failure is conceptually separated into two clinical subtypes: systolic heart failure and diastolic heart failure, with much overlap between the two. The American Heart Association (AHA) and American College of Cardiology (ACC) guidelines define heart failure related to systolic dysfunction (also known as heart failure with reduced ejection fraction [HFrEF]) as a left ventricular ejection fraction (LVEF) less than 40%. Diastolic heart failure (also known as heart failure with preserved ejection fraction [HFpEF]) is a pathologic condition involving normal or near-normal systolic function with failure of ventricular relaxation and consequent high filling pressures, which may exist in over half of older individuals with heart failure. HFpEF carries a prognosis similar to HFrEF.4,5

Heart failure is a progressive and multifaceted disease that begins long before symptoms and signs are evident. Guidelines approved by the AHA and ACC reflect a new classification system for heart failure that includes four categories: (1) patients at risk, (2) patients with asymptomatic left ventricular (LV) dysfunction, (3) patients with symptomatic heart failure, and (4) those with refractory heart failure.6 The number of patients with asymptomatic LV dysfunction is approximately fourfold greater than those with symptomatic heart failure.7 The main predisposing factors for heart failure in the United States include atherosclerotic coronary artery disease, hypertension, diabetes mellitus, dyslipidemia, obesity, along with cocaine, ethanol, and tobacco abuse. Hypertension precedes heart failure in up to 75%, particularly in African-Americans. Approximately two-thirds of patients with systolic heart failure have significant coronary artery disease. Those with diabetes mellitus have an increased risk of cardiac ischemic events and heart failure.8 High dietary sodium is associated with heart failure.9 Treatment should ideally be initiated in patients at risk to prevent disease progression. Control of hypertension greatly reduces the risk of development of heart failure, as does improvement of dyslipidemias in patients with atherosclerosis.10,11 Appropriate lifestyle changes, including substance abuse cessation, weight reduction, restriction of salt intake, and modest exercise programs reduce symptoms in heart failure and may delay progression. In particular, obesity leads to excessive lipid accumulation within the myocardium, is directly cardiotoxic, and causes LV remodeling with dilated cardiomyopathy.12 Substantial weight loss in patients with heart failure associated with obesity produces a reversal of many of the clinical manifestations and improves cardiac function.13 However, moderately overweight and obese patients have lower cardiovascular mortality in chronic heart failure, termed the obesity paradox, which is perhaps partly explained by cardiorespiratory fitness.14

Epidemiology
Heart failure is a leading cause of mortality of Western society and represents the fastest growing type of cardiovascular disease.15 About 6,100,000 individuals (approximately 2% of the population) in the United States have manifest heart failure, and almost 650,000 new cases are diagnosed annually.16 The incidence exceeds 10 per 1000 in people older than 65 years old, and the elderly comprise about 80% of the 1 million or so patients hospitalized with heart failure each year.17,18 Decompensated heart failure is a common reason for hospital admission in this age group and also for readmission within 30 days of discharge, with the emergency department (ED) a main portal of entry. Hospitalization for acute heart failure predicts a poor prognosis, with postdischarge mortality or rehospitalization rates reaching 45% within 60 to 90 days.19 Heart failure results in an annual estimated health care cost of approximately $40 billion.20 The aging population, coupled with improvements in the therapy of heart failure, will result in increased prevalence of this disease.21

Heart failure carries an approximate 50% mortality at 5 years after symptom onset, and one-third of patients with the most severe disease die within the first year after diagnosis.22 Heart failure disproportionately affects blacks when compared to white Americans, both in incidence and mortality, whereas all females have a survival advantage over males. Progressive hemodynamic deterioration accounts for approximately 50% of heart failure mortality, but sudden death resulting from malignant ventricular dysrhythmias occurs in up to half. Multiple medical therapies decrease the morbidity and mortality in heart failure by improving functional status and slowing progression of pump dysfunction. Implantable cardioverter-defibrillator (ICD) devices most reliably reduce the frequency of sudden death.23

The prognosis in heart failure is related to a number of factors, including age, LVEF, exercise tolerance, plasma norepinephrine and natriuretic peptide levels, cardiothoracic ratio on chest radiograph, anemia, hemoglobin A1c level, and renal function, as well as resting heart rate (HR), electrocardiogram (ECG) evidence of LV hypertrophy, atrial fibrillation, or presence of ventricular dysrhythmias.24,25 Renal dysfunction is a particularly important comorbidity in heart failure, with our understanding of the bidirectional interactions between the heart and kidney still limited.30 One-third to one-half of patients with heart failure have some degree of renal insufficiency, which is one of the strongest predictors of mortality.31 Treatment of comorbid conditions in heart failure may have a huge impact on the primary disease.32
Anatomy and Physiology

A complex neurohormonal regulatory relationship exists between the heart and multiple organ systems. Feedback loops mediated through a variety of vasoactive substances secreted by the heart, autonomic nervous system, kidneys, adrenals, lungs, and vascular endothelium are most important. Perturbations of function in any of these organs affect the others (Fig. 71.1). Accordingly, the cardiovascular system should be viewed as a dynamic one, continually adapting to optimize organ perfusion. Dysfunction of the heart or any component of the cardiopulmonary system initiates adaptive neurohormonal activation of the sympathetic nervous system, renin-angiotensin-aldosterone system (RAAS), natriuretic peptides, endothelin (ET), vasopressin, and other regulatory mechanisms. Neurohormonal activation initially compensates for circulatory system dysfunction. These mechanisms eventually lead to increased mechanical stress on the failing heart, however, causing maladaptive electrical and structural events, progressive cardiac fibrosis with apoptosis, and further impairment of systolic and diastolic function. This creates a vicious cycle of increasing myocardial dysfunction causing further neurohormonal modulation, leading to a progressive downward spiral. The degree of myocardial dysfunction depends on both the amount of primary myocardial disease and other pathologic conditions, particularly in the pulmonary, renal, and peripheral vascular systems. Understanding these underlying compensatory mechanisms is leading to progressive improvement in the management of heart failure, with a shift from a hemodynamic to a neurohormonal model.

Cellular Mechanisms

The heart is composed of a mass of individual striated muscle cells (myocytes) that form a branching syncytium. Each myocyte contains an intracellular tubular system termed the sarcoplasmic reticulum and numerous cross-banded strands termed myofibrils that traverse the length of the myocyte. Myofibrils, in turn, contain multiple subunits called sarcomeres, which form the basic functional unit of myocardial contraction. Sarcomeres occupy approximately 50% of myocardial cell mass and are composed of contractile proteins actin and myosin along with regulatory proteins troponin and tropomyosin. These proteins are surrounded by invaginations of the myocardial cell membrane (sarcolemma) and sarcoplasmic reticulum.

The sarcomere ranges in length from 1.6 to 2.2 µm, depending in part on the tension exerted on the muscle before contraction (preload). Sarcomere contraction occurs when thin, double-helix actin is exposed to thick myofilament myosin. Contraction, as well as relaxation, is controlled by calcium ion (Ca²⁺) release from the sarcoplasmic reticulum. When intracellular Ca²⁺ is increased, it binds to the contraction regulatory protein troponin, which

![Fig. 71.1. The neurohormonal model of heart failure describes a complex interdependence among many organ systems in which a functional disturbance in any component causes complex compensatory changes in the others that are eventually maladaptive. Correction of organ system dysfunction by medications and other interventions may result in correction of these perturbations.](image-url)
causes a conformational change in tropomyosin that exposes actin to myosin. In the presence of adenosine triphosphate (ATP), linkages between actin and myosin are rapidly made and broken, causing the actin to slide along the myosin filaments. This process generates muscle tension and ultimately myocyte contraction. A decrease in intracellular Ca\(^{2+}\) by sarcoplasmic reticulum reaccumulation reconfigures the tropomyo-tropomyosin complex in such a way that myosin and actin linkages are broken, allowing sarcomere relaxation. Intracellular ionic calcium is thus the principal mediator of the heart's inotropic state and is mainly stored and regulated by the sarcoplasmic reticulum. Most positive inotropic agents, including digitalis and catecholamines, act by increasing availability of intracellular calcium. On the downside, increased intracellular calcium reduces diastolic relaxation.

### Cardiac Physiology

The normal cardiac index is 2.5 to 4.0 L/min/m\(^2\) at rest and is determined by contractility, preload, afterload, and HR. In normal hearts, the collective force of contraction of the cardiac chamber is the sum of forces generated by individual myocytes. Myocyte force is in turn a function of the ability of contractile proteins to generate power (inotropic state or contractility), as well as degree of sarcomere stretch at the start of contraction (preload). Stretching the sarcomere progressively toward its optimal length of 2.2 µm increases the force of contraction by allowing the maximum number of actin-myosin myofilament interactions. This forms the basis of the Frank-Starling relationship, which states that within physiologic limits, force of ventricular contraction is directly related to end-diastolic length of the myofibril. Contractility can be affected by multiple physiologic depressants (eg, hypoxia, hypercarbia, acidosis, ischemia) and pharmacologic agents (eg, antidiysrhythmic agents, calcium channel blockers, beta-blockers, alcohol) that decrease myocardial function. Correcting physiologic myocardial depressant factors and discontinuing unnecessary medications with negative inotropic properties are important first steps in managing heart failure. Inotropic agents enhance contractility and may improve hemodynamics both acutely (such as with catecholamines) and chronically (such as with cardiac glycosides).

**Preload** is the amount of force stretching the myofibril before contraction. In the intact ventricle, preload is produced by venous return into the chamber, resulting in stretch of the myofibrils constituting the chamber walls. The volume filling the chamber also results in development of pressure that can be measured in either ventricle. The pressure measured inside a chamber is determined by both the volume stretching the wall and compliance characteristics of the muscle. For this reason, ventricular pressure is only an indirect reflection of preload. Changes in compliance occur acutely with ischemia or chronically with hypertrophy, and may substantially alter the relationship between chamber volume, pressure, and preload (Fig. 71.2).

Optimal preload is the filling pressure that stretches ventricular myofibrils maximally and leads to greatest stroke output per contraction. The actual optimal preload is unique for each patient because it is affected by LV loading conditions and compliance characteristics. For example, patients with acute myocardial infarction (AMI) tend to have a stiffer, less compliant left ventricle. In these patients, optimal LV pressure ranges are higher. No matter the inotropic state of the ventricle, optimizing preload results in maximum stroke output for that ventricle (Fig. 71.3). Ventricles with normal compliance accommodate larger volumes before the chamber pressure rises. Accordingly, if pressure is used to estimate preload, the normal ventricle has more dramatic increases in stroke output for similar increases in filling pressure (steeper Starling curve). The risk of pulmonary edema increases when LV end-diastolic pressure rises significantly above normal ranges (6 to 12 mm Hg). In patients with low colloid osmotic pressures secondary to hypoalbuminemia, pulmonary edema may occur at even lower filling pressures.

**Afterload**, for clinical purposes, can be thought of as the pressure against which the heart must pump to eject blood. Blood pressure (BP) is determined by the product of cardiac output (CO) and systemic vascular resistance (SVR) (BP = CO × SVR). Hypertension is a major contributor to heart failure. Patients with heart failure and low cardiac output tend to maintain BP through peripheral vasoconstriction mediated mainly by endogenous catecholamines and the RAAS. Afterload represents the mural tension on myocardial cells during contraction and is determined by the total peripheral vascular resistance and the cardiac chamber size. Peripheral resistance is affected by the total cross-sectional area of the circulation, blood viscosity, and other factors. The arterioles are the major resistance vessels in the circulation. Flow is directly proportional to the fourth power of the vessel radius (Poiseuille's law). The larger the ventricular cavity, the more mural tension and thus myocardial work is required during contraction (law of Laplace).

Failing ventricles have difficulty overcoming increases in peripheral resistance, instead dilating further, increasing end-diastolic volume to maintain SV, even with decreasing EF (preload
Increased Systemic Vascular Resistance

Increased SVR results in redistribution of a subnormal cardiac output away from skin, skeletal muscles, and kidneys to maintain normal blood flow to the brain and heart. This elevated afterload also greatly increases myocardial work.

Development of Cardiac Hypertrophy

LV remodeling describes the changes in ventricular mass, volume, shape, and composition in response to mechanical stress and systemic neurohormonal activation. Development of cardiac hypertrophy is the primary chronic adaptation of the heart to compensate for pump failure. This hypertrophy occurs mainly by increasing the number of myofibrils per cell, because the heart has very limited ability to produce new cells (hyperplasia). New myofibrils arrange in series in response to an increase in chamber volume (leading to dilation over time) and in parallel when responding to higher pressure loads (leading to increased chamber wall thickness). LV hypertrophy leads to a less efficient round LV chamber compared to the normal elliptical shape. In addition to myofibril hypertrophy, mitochondria mass expands, leading to additional ATP provision for the expanded myofibril mass. However, impaired mitochondrial function is recognized in heart failure, with reduced energy production and higher oxidative stress.

Initially, hypertrophy leads to improved function of each myocardial cell but at a higher energy cost. Hypertrophy is associated with myosin and other sarcomere protein isoform shifts, with related slowing of contraction, prolongation of time to peak tension, and reduced rate of relaxation.

With the continued influence of volume overload, myofibril mass expands more than mitochondrial mass. Relative capillary blood flow is also reduced, leading to progressive myocyte death with fibrosis and increased stress on the remaining myocytes. This leads to extracellular matrix expansion, which is one of the negative effects of pathological LV remodeling. Thus the remodeling response, if allowed to continue, eventually becomes maladaptive, accelerating myocyte death, reducing microvascular perfusion, increasing extracellular collagen, and reducing pump function.

Physiologic Mechanisms

Increase in Stroke Volume

Increased SV occurs in response to increase in preload (Frank-Starling mechanism). This compensatory mechanism is prompt and effective in improving cardiac output in response to acute systemic demands. It is a limited response, however, because myofibril stretch to a sarcomere length beyond 2.2 μm does not further increase stroke output and may actually reduce it. Also, this mechanism greatly increases myocardial energy demand, which may lead to dysfunction in the setting of significant coronary artery disease.

Increased Systemic Vascular Resistance

Increased SVR results in redistribution of a subnormal cardiac output away from skin, skeletal muscles, and kidneys to maintain normal blood flow to the brain and heart. This elevated afterload also greatly increases myocardial work.
intravascular volume and decrease osmolality. This potentiates effects of angiotensin II and norepinephrine.

Heart failure results in a generalized stimulation of sympathetic activity and inhibition of parasympathetic tone. Increased sympathetic outflow results in release of epinephrine and norepinephrine from the adrenal glands, as well as norepinephrine at peripheral sympathetic nerve endings. These elevated catecholamine levels stimulate surface receptors in the heart and blood vessels, increasing cardiac contractility, HR, and vascular tone. The resulting increased vascular tone augments preload through venous contraction, as well as afterload by arterial vasoconstriction. Acutely, arterial BP is improved and cardiac output increased by catecholamines. Chronically, a decrease in the number and affinity of surface catecholamine receptors occurs in myocardial tissue, reducing responsiveness to epinephrine and norepinephrine. Elevated catecholamines adversely affect myocardial perfusion, leading to progressive cardiac cell death and fibrosis.

Renal Neurohormonal Response
Decreased glomerular perfusion results in reduced renal excretion of sodium, causing renal arteriolar and adrenergic receptors to stimulate renin release by the juxtaglomerular apparatus. Renin facilitates the conversion of angiotensinogen to angiotensin I, which is further converted to angiotensin II by angiotensin-converting enzyme (ACE). Angiotensin II is a potent vasoconstrictor and an important stimulus for aldosterone release by the adrenal cortex. Aldosterone increases renal sodium retention and potassium excretion. Renal adaptation to hyperperfusion occurs mainly through production of vasodilatory hormones, such as prostacyclin, along with prostaglandin I₂ (PGI₂) and prostaglandin E₂ (PGE₂). Aspirin and other nonsteroidal antiinflammatory drugs (NSAIDs) interfere with prostaglandin synthesis by inhibiting cyclooxygenase. Therefore, except for the useful antiplatelet effect of aspirin, NSAIDs optimally should be avoided in patients with chronic heart failure, because they may contribute to acute renal insufficiency, with concomitant salt and water retention.

Vascular Endothelial Neurohormonal Response
Endothelial function locally regulates vasomotor tone. A family of endothelins are produced by endothelial and smooth muscle cells, as well as neural, renal, pulmonary, and inflammatory cells. This occurs in response to hemodynamic stress, hypoxia, catecholamines, angiotensin II, and many inflammatory cytokines. ET-1 is the most important ET and the most potent vasoconstrictor known. ET-1 plasma levels are elevated in heart failure, correlate with symptoms as well as hemodynamic stress, and are associated with adverse prognosis.

Nitric oxide (NO) is synthesized from L-arginine and one of three subforms of NO synthase. NO is produced in almost all tissues, and plays a critical role in homeostasis of cardiac function. NO exerts its biologic signaling through production of cyclic guanosine monophosphate (cGMP), which is broken down by cyclic nucleotide phosphodiesterases (PDEs). PDF inhibitors like sildenafil (Viagra) reduce NO degradation. Reduced synthesis or increased degradation of NO at the endothelial level is detrimental in heart failure. NO-mediated endothelial dysfunction may represent the earliest stage of target organ damage, which ultimately leads to hypertensive heart disease and heart failure.

Pathophysiology
Maladaptive Changes in Heart Failure
Ventricular remodeling includes cardiac dilation, reactive hypertrophy, progressive fibrosis, and changes in wall conformation, all of which correlates with poor clinical outcomes in heart failure. Serial measurements of various biomarkers may serve as surrogate markers of ventricular remodeling. Reverse remodeling is a concept in which progressive LV dysfunction is not simply arrested but also partially reversed. Various antihypertensive therapies, including beta-blockers, ACE inhibitors, angiotensin receptor blockers (ARBs), and aldosterone antagonists allow regression of LV hypertrophy and reduce the rate of sudden cardiac death. Targeting the myocardial interstitium, mitochondrial dysfunction, and improving metabolic impairment in heart failure are other areas of intense interest.

Primary Disease Processes Resulting in Heart Failure
Heart failure can result from primary diseases of coronary arteries, myocardium, cardiac valves, pericardium, peripheral vessels, or lungs. Heart failure frequently has multifactorial causes. Often, determination of the causes of heart failure is simpler early in its course than during later stages.

Coronary Artery Disease. In developed countries, atherosclerotic coronary artery disease remains the leading cause of heart failure, which is present in almost 70% of patients in multivector heart failure trials. Acute coronary thrombosis leads to focal myocardial necrosis, with resultant fibrosis and scarring. This process leads to areas of dyskinesis that result in decreased EF. Aneurysmal dilation of infarcted areas with paradoxical wall motion during systole may disproportionately decrease EF. When approximately 40% of the LV muscle mass is acutely infarcted, cardiogenic shock ensues. Transient loss of contractile function may result from episodes of myocardial ischemia that do not cause frank necrosis, or from an ischemic zone surrounding the infarct. This “myocardial stunning” may persist for several days. Owing to improved treatment of acute coronary syndromes, the rates of secondary death and heart failure are decreasing.

Chronic coronary insufficiency leads to a more diffuse myocardial fibrosis termed ischemic cardiomyopathy. The role of late coronary revascularization in reducing heart failure-associated morbidity and mortality remains controversial. Diseases affecting the coronary microcirculation, such as vaso-occlusive sickle cell anemia and diabetes mellitus, result in similar pathology.

Cardiomyopathy and Myocarditis. Cardiomyopathies are a group of disease processes that primarily affect myocardium. Myocardial diseases resulting from coronary, valvular, and pericardial pathologies are excluded. Cardiomyopathy is categorized as primary if cause is unknown, or secondary if some etiology is identified. Clinically, patients with cardiomyopathy tend to have three forms—dilated, hypertrophic, or restrictive—each associated with heart failure. Dilated cardiomyopathy is much more common than the other two and is the second most common cause of heart failure. The specific cardiomyopathies and myocarditis, which may cause heart failure, are discussed in Chapter 72.

Valvular Heart Disease. Cardiac valvular disease is the third leading cause of heart failure, after ischemic heart disease and dilated cardiomyopathy. Most acute valvular dysfunction involves either the mitral or aortic valve and usually results in severe regurgitation. Acutely stenotic lesions are predominantly restricted to mechanical catastrophes of prosthetic valves. These patients may be in extremis with fulminant pulmonary edema.

Mitrail insufficiency and aortic stenosis are most commonly associated with chronic heart failure. Knowledge of the precise valvular pathology may have important implications for emergent heart failure therapy. For example, patients with decompensated aortic stenosis should generally not receive vasodilator agents, because flow cannot increase across a fixed obstruction. These
patients may become hypotensive owing to reduced preload, with resultant decreased systemic and coronary perfusion. On the other hand, patients with mitral regurgitation benefit greatly from vasodilators, which improve antegrade flow by reducing afterload. Valvular disease is discussed in Chapter 73.

**Pericardial Diseases.** Pericardial diseases may significantly affect ventricular function by decreasing cardiac output and increasing intracardiac pressures. In particular, cardiac tamponade may cause dyspnea and hypoperfusion not easily distinguished clinically from heart failure. ED use of bedside ultrasound has great usefulness in quickly identifying this problem. Pericardial diseases are fully discussed in Chapter 72.

**Pulmonary Disease.** Chronic obstructive pulmonary disease (COPD) has a prevalence of 20% to 30% in heart failure and may obscure recognition. Pulmonary dysfunction reduces myocardial oxygen supply, while cardiac output increases because tissue is being perfused with suboptimally oxygenated blood. Hypoxia leads to pulmonary arteriolar vasoconstriction, reducing lung vascular bed area and elevating pulmonary artery pressures. Chronic increases in pulmonary arterial pressure lead to right ventricular (RV) hypertrophy and dilation. When compensatory mechanisms fail, the patient develops right-sided heart failure (cor pulmonale), usually with LV output preserved, at least at rest. Causes of acute pulmonary hypertension, such as a large pulmonary embolus, may precipitate sudden systemic hypotension and death, in part due to decreased LV priming.

Distinguishing primary pulmonary disease causing predominantly right-sided heart failure from LV failure with secondary right-sided dysfunction is clinically challenging. Wheezing or rhonchi may be present in both entities. The chest radiograph may be difficult to interpret because both presentations cause interstitial changes. Hyperinflation depresses the diaphragm, which elongates the cardiac silhouette and may mask cardiomegaly. Competition for intrathoracic space reduces lung capacity in patients with chronic heart failure. Natriuretic peptide levels are only slightly elevated in primary pulmonary disease compared with much higher levels in LV failure.56,57

**Classification of Heart Failure**

Many different methods of classifying heart failure exist, including acute versus chronic, systolic versus diastolic, right versus left sided, and high versus low output. Early in heart failure, these may be useful clinical descriptors suggesting particular causes and treatment strategies.

**Acute Versus Chronic Heart Failure.** The prototypical case of acute heart failure involves a healthy person who develops a large myocardial infarction (MI) or acute valvular dysfunction. Chronic heart failure is best characterized by a disease state, such as dilated cardiomyopathy, with gradual deterioration of cardiac function. In acute heart failure, early presentation may be a result of systolic dysfunction and hypoperfusion, often with acute cardiogenic pulmonary edema (ACPE) resulting from sudden reduction in chamber compliance. Chronic heart failure usually arises with symptoms related to gradual fluid retention, with compensatory mechanisms adjusted so that normal perfusion exists, at least in the resting state. In clinical practice, approximately 80% of heart failure cases seen the ED involve acute decompensation of chronic heart disease.58,59

**Systolic Versus Diastolic Dysfunction.** Systolic heart failure, or HFrEF, refers to contractility impairment, with stroke output reduced and forward flow compromised. Systolic dysfunction is typically caused by myocyte damage from etiologies, such as MI or myocarditis. Asymptomatic LV systolic dysfunction is much more common than symptomatic systolic heart failure. Almost all cases of systolic dysfunction also involve some degree of diastolic dysfunction.

Diastolic heart failure, or HFrEF, indicates a primary problem with ability of the ventricles to relax and fill normally. In some cases, normal or even supranormal systolic function is preserved. Echocardiographic and nuclear imaging techniques demonstrate that up to half of patients with congestive heart failure have EFs more than 50% and experience primarily diastolic dysfunction, and this proportion increases with age.60,61 Asymptomatic diastolic dysfunction is much more common than asymptomatic systolic dysfunction. Diastolic dysfunction is the predominant pathophysiology in hypertrophic and restrictive cardiomyopathies, valvular aortic stenosis, and, most important, hypertension.

Diastolic dysfunction occurs predominantly as a result of one of three mechanisms: (1) impaired ventricular relaxation, (2) decreased ventricular wall thickness, or (3) accumulation of myocardial interstitial collagen. Impaired lusitropic (relaxation) capacity of the myocardium leads to higher ventricular filling pressure, resulting in congestive symptoms. Myocardial relaxation is an active, energy-requiring process. Failure of myocytes to relax may be secondary to low intracellular energy stores. Physiologic stresses causing increased cardiac demands can precipitate lusitropic abnormalities. In chronic renal disease, mortality is higher in diastolic than systolic heart failure.62 In addition, systolic contractile dyssynchrony occurs in one-third of diastolic heart failure patients, whereas diastolic dyssynchrony is present in more than half, with therapeutic implications.63,64

As with the other classification schemes, most patients with heart failure have components of both systolic and diastolic dysfunction, with the predominant type allowing specific treatment strategies. For example, patients with predominantly diastolic dysfunction have the advantage of intact myocardial contractile function. Stiffer hearts, however, have steep pressure-volume curves. Therefore, small reductions in diastolic filling volume, as may occur with vasodilator or diuretic therapy, may markedly decrease ventricular filling and compromise stroke output (see Fig. 71.3).

**Right-Sided Versus Left-Sided Heart Failure.** The notion that one cardiac chamber can fail independently of the others is somewhat artificial. The right and left circulations are connected and output from the two sides must be equal. Furthermore, the right and left ventricles share an interventricular septum, and dysfunction in one chamber may have an impact on the other. For example, acute right-sided heart failure from pulmonary hypertension secondary to acute respiratory failure causes bulging of the interventricular septum into the LV chamber. This so-called “septal shift” results in decreased LV preload and low cardiac output that is volume responsive. Chronic left-sided heart failure leads to pulmonary hypertension with resultant right-sided heart failure.65,66 In addition, cardiac biochemical changes, including abnormal catecholamine response, affect all chambers.

The terms have usefulness in identifying the predominant clinical presentation. Fluid accumulation “behind” the involved ventricle is responsible for many of the clinical manifestations of heart failure. For example, LV failure leads primarily to pulmonary congestion with symptoms mostly of dyspnea and orthopnea. Patients with right-sided heart failure have symptoms of systemic venous congestion, such as pedal edema and hepatomegaly.

When previously healthy patients have acute pathology, the concept of left- versus right-sided heart failure may be clinically useful. Patients with acute MI may have ACPE; yet unlike patients with chronic heart failure, they may not have jugular venous distention or pedal edema because central venous pressure may remain within normal limits. A chest radiograph reveals evidence
may be necessary for adequate LV preload and restoration of BP. Resuscitation, followed by inotropic support with norepinephrine, tension that is often symptomatic. High volume, rapid crystalloid preload). These patients have right-sided heart failure with hypotension that is often symptomatic. High volume, rapid crystalloid resuscitation, followed by inotropic support with norepinephrine, may be necessary for adequate LV preload and restoration of BP.

**High-Output Versus Low-Output Failure.** High-output failure refers to a hyperdynamic state with supranormal cardiac output and low arteriovenous oxygen difference (decreased oxygen extraction ratio). The hyperdynamic state may result from increased preload (eg, renal retention of salt and water, or excess mineralocorticoids), decreased SVR (eg, arteriovenous fistulas, pregnancy, cirrhosis, severe anemia, beriberi, thyrotoxicosis, Paget’s disease, or vasodilator medications), increased beta-sympathetic activity, or persistent tachycardia. A persistent hyperdynamic state results in myocardial damage over time. Early recognition of the hyperdynamic state may allow effective therapy of the underlying condition, thus avoiding development of heart failure. As the condition progresses, myocardial dysfunction with circulatory overload is superimposed, resulting in symptom progression. At some point, cardiac output becomes normal or even low, and is indistinguishable from classic heart failure.

Low-output failure is the more typical variety of heart failure and occurs as a result of entities such as ischemic heart disease, dilated cardiomyopathy, valvular disease, and chronic hypertension. Low cardiac output (systolic dysfunction), high filling pressures (diastolic dysfunction), and an increased systemic oxygen extraction ratio (widened arteriovenous oxygen difference) characterize this more commonly encountered form of heart failure.

**Precipitating Causes of Heart Failure and Exacerbating Factors**

When cardiac decompensation occurs due to an acute precipitating cause, intervention can be directed at the specific precipitating factor(s). Prognosis for patients who present due to a specific cause is much better when compared to intrinsic progression of cardiac failure. Causes of acute cardiac decompensation are in Box 71.1. In chronic heart failure, the most common cause of decompensation is iatrogenic or relative decrease in intensity of treatment, including drug therapy, dietary sodium increase, limited physical activity, or a combination of these factors.

**Sodium and Volume Excesses**

Decompensation may be precipitated by plasma volume expansion due to increased sodium ingestion, most often a result of dietary noncompliance, as well as by excessive crystalloid infusion or transfusion. Noncompliance with renal dialysis, in particular, is a very common cause of heart failure in ED patients.

**Systemic Hypertension**

Sudden elevation of arterial pressure acutely increases afterload, which may precipitate abrupt onset of heart failure. This is particularly common when antihypertensive therapy is discontinued. Emotional upset can dramatically increase afterload as well as precipitate coronary vasospasm, with the extreme example being acute stress cardiomyopathy (Takotsubo syndrome; see Chapter 68).

**Myocardial Infarction and Ischemia**

A new ischemic event may precipitate heart failure by impairing contractility and decreasing LV compliance. Pulmonary edema may occur quickly in this setting, especially when large areas of myocardium are involved. In the compromised heart, even local ischemia may precipitate heart failure. Occult acute coronary syndrome is common, particularly in the elderly, and should be considered in any heart failure exacerbation. The presence of heart failure on admission in patients with acute coronary syndromes is associated with increased short- and long-term rates of death and MI.

**Systemic Infection**

Infection results in increased systemic metabolic demands. The sepsis syndrome is associated with a reversible form of myocardial depression, mediated by various cytokines, including interleukin (IL)-1, and IL-6, as well as tumor necrosis factor. Proinflammatory cytokines, such as tumor necrosis factor alpha and IL-6, also play an important pathogenic role in chronic heart failure.

**Dysrhythmias**

Both tachydysrhythmias and bradydysrhythmias can severely affect cardiac output, especially when acute. Tachydysrhythmias compromise diastolic filling time, reduce cardiac output, and impair coronary perfusion. The tachycardia also results in increased myocardial oxygen demand. These factors may precipitate ischemia, which may further impair contractility and exacerbate heart failure.

The prevalence of atrial fibrillation in patients with heart failure increases from less than 10% in New York Heart Association (NYHA) functional class I to approximately 50% in NYHA functional class IV. Neurohormonal alterations, electrophysiologic changes, and mechanical factors create an environment in which heart failure predisposes to atrial fibrillation and atrial fibrillation exacerbates heart failure. New-onset atrial fibrillation or other dysrhythmias may affect coordinated atrial priming of the ventricular pump and reduce preload, especially in disease states with reduced ventricular compliance. Significant bradydysrhythmias

---

**Box 71.1**

Common Precipitating Causes of Acute Heart Failure

- Sodium and volume excess
- Systemic hypertension
- Myocardial infarction (MI) or ischemia
- Systemic infection
- Dysrhythmias
- Acute hypoxia or respiratory problems
- Anemia
- Pregnancy
- Thyroid disorders
- Acute myocarditis
- Acute valvular dysfunction
- Pulmonary embolus
- Sympathomimetic or alcohol excess
- Excessive exertion or trauma
- Pharmacologic complications

---
may also reduce cardiac output simply by reducing the number of systolic ejections per minute \( (CO = SV \times HR) \).

**Acute Hypoxia and Respiratory Problems**

COPD exacerbations, increased air pollution, and respiratory tract infections are very important precipitating factors for heart failure exacerbation. Pulmonary infection, which is more common in patients with pulmonary vascular congestion, may add hypoxia to the metabolic stressors of fever, tachycardia, and increased tissue perfusion requirements.

**Anemia**

With chronic anemia, increased cardiac output maintains tissue oxygen delivery. Anemia increases in prevalence with increasing severity of heart failure, especially with declining renal function and increasing age. Anemia is associated with poorer survival in heart failure, with greater disease severity, greater LV mass index, and higher hospitalization rates. Abrupt exacerbations of anemia increase systemic perfusion demands and, especially if coupled with reduced coronary oxygen delivery, may prompt onset or exacerbation of heart failure.

**Pregnancy**

Cardiac output is normally increased significantly during pregnancy, which may lead to decompensation with underlying valvular disease or other cardiac pathologies. Peripartum cardiomyopathy is a type of dilated cardiomyopathy that may occur late in pregnancy or more commonly in the early postpartum period.

**Thyroid Disorders**

Heart failure may be a clinical manifestation in patients with previously compensated cardiac disease who develop hyperthyroidism. Hypothyroidism also adversely affects myocardial pump function. Restoration of normal thyroid function may reverse abnormal cardiovascular hemodynamics.

**Acute Myocarditis**

A variety of infectious and inflammatory myocardial diseases, including viral agents and acute rheumatic fever, may precipitously impair cardiac contractility.

**Acute Valvular Dysfunction**

Almost all causes of acute heart failure resulting from cardiac valve dysfunction are secondary to aortic or mitral insufficiency. Mitral valve papillary muscle dysfunction or rupture may result from acute MI, whereas acute aortic insufficiency, although uncommon, can be precipitated by acute bacterial endocarditis or aortic dissection. Rarely, acute valvular stenosis may occur, usually as a consequence of acute dysfunction of a prosthetic valve.

**Pulmonary Embolus**

The pulmonary hypertension and hypoxia that accompany pulmonary embolus may cause acute heart failure. This diagnosis should be entertained in patients who have unexplained heart failure and risk factors for pulmonary embolism.

**Sympathomimetic or Alcohol Excess**

Pheochromocytoma and other states associated with high sympathomimetic outflow may precipitate heart failure, as may cocaine and other sympathomimetic drugs of abuse, by a similar mechanism. Although 1 to 2 ounces of alcohol a day reduces risk of heart failure and other cardiovascular mortality, heavy consumption greatly increases risk of cardiac arrhythmias, dilated cardiomyopathy, heart failure, stroke, and overall mortality. Use can cause sudden decompensation. Modest coffee consumption conversely, may actually reduce risk of heart failure.

**Excessive Exertion or Trauma**

Increased physical activity may lead to cardiac decompensation, particularly in patients with significant heart failure. Trauma as well as critical illness and injury in general also increase demand on the heart, precipitating acute heart failure, although the mechanisms are multifactorial.

**Pharmacologic Complications**

Beta-blockers and calcium channel blockers have negative inotropic effects that may precipitate overt heart failure with excessive administration. Many antidysrhythmic agents have similar effects. Glucocorticoids, NSAIDs, vasodilator medications, and others may result in sodium retention with substantial increases in plasma volume that may precipitate heart failure. NSAIDs in particular interfere with prostaglandin synthesis through cyclooxygenase inhibition, thereby impairing renal homeostasis in patients with heart failure. They also interfere with the effects of diuretics and ACE inhibitors. Nonadherence to medication regimens for hypertension, heart failure, or ischemia is the most common pharmacologic cause of cardiac decompensation.

**CLINICAL FEATURES**

**History**

The presence and character of dyspnea, chest pain, previous heart disease, cardiac catheterization, surgery, current medications (plus adherence), and possible intercurrent illness should be explored. Paroxysmal nocturnal dyspnea results from pulmonary congestion precipitated by plasma volume expansion that occurs during recumbency, because interstitial edema is reabsorbed into the circulation. Orthopnea occurs through the same mechanism, with the supine position causing significant increases in diastolic filling pressure. Symptoms abate after the patient stands or props up the trunk and venous return decreases. Nocturia results from the same pathophysiologic process. Many historical features increase the likelihood of heart failure. Most predictive is a past history of heart failure or paroxysmal nocturnal dyspnea, and absence of dyspnea on exertion reduces the likelihood of chronic heart failure.

**Physical Examination**

Most heart failure patients are hypertensive, which is prognostically preferable to normal or low BP. Clammy, vasoconstricted patients with a thready pulse and delayed capillary refill may have systemic hypoperfusion despite adequate BP, which is maintained by intense vasoconstriction. Noninvasive assessment of BP in the vasoconstricted patient with low cardiac output can be inaccurate. If available, intra-arterial pressure monitoring may more accurately reflect the systemic hemodynamic state and guide the choice of therapy in hypotensive heart failure patients.

Most patients with ACPE are diaphoretic because of intense sympathetic activation. Patients with pulmonary congestion secondary to heart failure develop interstitial and alveolar pulmonary edema, causing reduced pulmonary compliance and decreased functional residual capacity. Clinical findings include diffuse rales,
which may be absent with decreased ventilation in more agonal patients. Peribronchial edema may cause wheezing or rhonchi, which can mimic bronchospastic disease (“cardiac asthma”). A positive response to bronchodilator therapy does not exclude heart failure. Jugular venous distention is present in approximately 50% of cases of heart failure, and one-third of patients have peripheral edema. An S3 gallop may be present in up to 25% but is often difficult to hear. Physical examination of patients with ACPE resulting from acute MI may identify surgically correctable lesions, such as acute mitral regurgitation or ventricular septal defect.

These common clinical findings of chronic heart failure are prevalent among patients with ACPE, because most patients have acute exacerbations superimposed on chronic underlying disease. Jugular venous distention, pedal edema, and cardiomegaly may be absent in previously healthy individuals with pulmonary edema resulting from an initial episode of acute heart failure. The presence of a third heart sound significantly increases the likelihood of heart failure, whereas absence of rales decreases the likelihood.93

DIFFERENTIAL DIAGNOSES

Careful consideration of the differential diagnosis of heart failure is symptom based. The most common manifestation of acute heart failure is respiratory distress caused by pulmonary edema. The differential diagnosis, therefore, includes non-cardiogenic pulmonary edema, exacerbation of COPD or asthma, pulmonary embolus, pneumonia, tension pneumothorax, cardiac tamponade, anaphylaxis, and other causes of acute respiratory distress. These etiologies may cause hypoperfusion, as can sepsis syndrome, hypovolemia, and hemorrhage. The NYHA classification system is a time-honored categorization for patients with chronic heart failure based on degree of activity causing symptoms (Box 71.2).

DIAGNOSTIC TESTING

An upright chest radiograph helps distinguish cardiogenic pulmonary edema from other causes of dyspnea. An enlarged cardiac silhouette is seen in 70% of cases. A normal heart size suggests ACPE in a patient without prior heart failure, diastolic dysfunction, COPD, or noncardiogenic pulmonary edema. An early ECG for arrhythmia recognition and management is important, as well as for identification of acute coronary syndrome. Absence of cardiomegaly on chest radiography and a normal ECG greatly decrease the likelihood that heart failure is causing the presentation.98 Obtaining a complete blood count (CBC) to evaluate for anemia and a basic metabolic panel to determine electrolyte status as well as renal function is generally useful. Cardiac troponins help evaluate for ongoing myocyte injury, which may be clinically silent.

In most cases, and particularly when the diagnosis of heart failure is unclear, natriuretic peptide levels are helpful. Pre-proBNP is synthesized in the ventricles in response to myocyte stretch, with release and enzymatic cleavage to N-terminal–proBNP (NT-proBNP) and BNP. NT-proBNP and BNP levels help identify patients with heart failure and may improve evaluation of patients in the ED with undifferentiated dyspnea.99 The “breathing not properly” BNP Multinational Study was a prospective evaluation of patients who came to the ED with acute dyspnea. BNP levels above 500 pg/mL were highly associated with heart failure (likelihood ratio [LR] = 8.1), but levels of 100 to 500 pg/mL were generally indeterminate (LR = 1.8). A low BNP level (<100 pg/mL) indicated that heart failure was highly unlikely (LR = 0.13).101 ED use of BNP or NT-proBNP assays aids diagnosis of heart failure and can reduce admission rates, as well as length of hospitalization in acute dyspnea.101,102

Natriuretic peptide levels correlate with ventricular function, NYHA classification, and prognosis, with BNP probably the most useful.101 There is often a disconnect between the perceived severity of heart failure by clinicians and the degree of BNP elevation, yet BNP levels are better predictors of 90-day outcome than physician judgment.102 Natriuretic peptide level guided therapy reduces all-cause mortality, as well as heart failure rehospitalization, and provides a strong measure of therapeutic response in chronic heart failure compared with usual care.102 Mildly elevated BNP levels may also be seen in right-sided heart failure related to cor pulmonale or pulmonary embolism. BNP and troponin levels are only slightly elevated in patients with end-stage renal disease, and in this setting marked elevation reflects ventricular dysfunction.104 Admission BNP and troponin levels are independent predictors of in-hospital mortality and other adverse outcomes in acute decompensated heart failure.105,106

Pulmonary artery catheterization in severe symptomatic heart failure increases anticipated adverse effects but does not affect overall mortality or duration of hospitalization.107 Noninvasive impedance cardiography appears to be an effective and developing technology to measure cardiac output and other hemodynamic variables in heart failure, although it cannot reliably measure LV filling pressures.108,109 Bedside ultrasound can be an important ED screening tool in heart failure, with attention to wall motion abnormalities, EF, and valvular function, as well as exclusion of cardiac tamponade.110 Echocardiography is similarly useful and can provide detailed measures of LV function and determine structural heart disease.111 Point-of-care ultrasound is also superb in recognizing pulmonary edema on lung examination, with very high sensitivity and specificity to diagnose ACPE. Lung ultrasonography has higher accuracy for diagnosis of acute decompensated heart failure in undifferentiated dyspneic patients than clinical evaluation, chest x-ray, or natriuretic peptides.112 It can also recognize pneumonia, pleural effusion, and decompensated COPD or asthma.112 Multidetector computed tomography coronary angiography can distinguish ischemic from other forms of cardiomyopathy but is rarely useful in acute heart failure. Cardiac magnetic resonance and radionuclide imaging have an expanding role in evaluating chronic heart failure but no utility in the acute setting.

MANAGEMENT

Of patients with heart failure in the ED, about 20% are experiencing their first episode of heart failure, and 80% have had prior hospital visits for the same condition. The approach to acute heart failure focuses on (1) determining the underlying cardiac pathology, (2) identifying the precipitant(s), and (3) mitigating the decompensation. The primary therapeutic goals are to improve respiratory gas exchange, maintain adequate arterial saturation, and decrease LV diastolic pressure while maintaining adequate cardiac and systemic perfusion.

The acute congestive state can be controlled by (1) reducing cardiac workload through decreased preload and afterload, (2)
reducing excessive retention of salt and water, and (3) improving cardiac contractility. Patients with acute heart failure may have a wide spectrum of symptoms and signs ranging from mild dyspnea on exertion to full-blown cardiogenic shock with hypotension and concomitant respiratory failure.

Acute Heart Failure

Pulmonary edema is classified clinically into cardiogenic and noncardiogenic forms. Most patients in the emergency setting with pulmonary edema have the acute cardiogenic variety, resulting mainly from elevated LV end-diastolic pressure, forcing a protein-sparse plasma ultrafiltrate across the pulmonary capillary membrane into the pulmonary interstitium. Large amounts of edema accumulate, leading to alveolar flooding. Up to 1 to 2 L may leave the plasma over a short time and create respiratory compromise. Most commonly, ACPE occurs with acute myocardial ischemia or infarction, cardiomyopathy, valvular heart disease, or hypertensive emergencies.

Patients with ACPE have substantially lower plasma volumes than control patients. These changes are reflected by initial hemconcentration as evidenced by higher hematocrits and colloid osmotic pressures. Despite the presence of pulmonary congestion, concomitant hypotension might need a fluid challenge to restore preload, cardiac output, systemic perfusion, and BP. Thus careful volume infusion with aliquots of normal saline is appropriate initial resuscitation for the hypoperfusing patient with ACPE.

In contrast, noncardiogenic pulmonary edema generally results from an alteration in the permeability characteristics of the pulmonary capillary membrane. The alteration may have such diverse causes as septic shock, inhalation injuries, drugs or toxins, aspiration syndromes, fat emboli syndrome, neurogenic causes, and high altitude.

Acute Heart Failure With Adequate Perfusion

Many patients with acute heart failure demonstrate adequate systemic perfusion with elevated BP because of activation of various compensatory mechanisms. The ability of the left ventricle to generate normal or elevated systolic pressures indicates the presence of considerable myocardial reserve and is associated with lower mortality in both acute and chronic heart failure. These patients should be quickly distinguished from those with pulmonary edema and evidence of hypoperfusion. Hypertensive pulmonary edema is easier to manage because afterload reduction with vasodilators is extremely effective.

Therapeutic interventions should decrease both preload and afterload. Excessive preload reduction may result in an abrupt decrease in cardiac output, however, which could cause hypotension. This occurs more readily in patients with less compliant hearts. Fluid challenge generally restores BP. Therapy for ACPE with adequate perfusion should begin with upright positioning, supplemental oxygen, nitrates, morphine sulfate, and loop diuretics (Fig. 71.5). This allows prompt improvement in most of these patients.

Oxygen and Ventilation

Most patients with significant pulmonary edema have hypoxemia and need high-flow oxygen by face mask if they are spontaneously...
breathing and if oxygen saturation as measured by pulse oximetry (\(\text{SpO}_2\)) is below 90%. Excessive oxygen therapy, however, may significantly increase afterload and worsen cardiac function in decompensated heart failure.69 The typical acid-base disturbance of acute heart failure is mixed. Patients with fulminant ACPE may have lactic acidosis, and many also have concomitant respiratory alkalosis resulting from the tachyphnea stimulated by metabolic acidosis, hypoxemia, and decreased pulmonary compliance. In more severe cases, respiratory acidosis ensues as the patient fatigues and respirations fail. The ratio of dead space to total ventilation (\(V_{\text{D}}/V_{\text{T}}\)) may be significantly increased owing to alveolar flooding. Patients with inadequate ventilation or with severe hypoxia that does not respond to supplemental oxygen will need ventilatory support. Noninvasive ventilation (NIV) techniques are effective in treating severely compromised, but not agonal, ACPE patients (see Chapter 2). Continuous positive airway pressure (CPAP) or biphasic positive airway pressure (BiPAP) applied by an adjustable, snugly fitting face mask increases functional residual capacity, improves oxygenation, reduces work of breathing, and results in decreased LV preload and afterload by raising intrathoracic pressure (Fig. 71.6). NIV provides earlier improvement in respiratory disease and related metabolic abnormalities than supplemental oxygen alone in ACPE and improves short-term mortality.100 Prehospital studies using CPAP in ACPE also demonstrate reduced intubation rates and mortality, reinforcing greater use in this arena.101,102 The addition of inspiratory pressure support (BiPAP) further reduces the work of breathing and more rapidly improves hypercarbia than CPAP alone.103 Most spontaneously breathing patients benefit greatly from these techniques when appropriately applied in conjunction with pharmacotherapy, and the majority of alert hypercarbic patients can be managed without mechanical ventilation.

Patients too ill for NIV are supported with bag-valve-mask assisted oxygenation in preparation for endotracheal intubation. Intubation is indicated for apneic patients and those with respiratory distress, agitation, or hypoxemia not responsive to high-flow oxygen or NIV. Mechanical ventilation with moderate levels of positive-end-expiratory pressure is safe in acute heart failure and may provide hemodynamic benefit through afterload reduction.104 Extracorporeal membrane oxygenation may have a rescue role in severe heart failure unresponsive to other therapies.105-106

![Diagram](image.png)

**Fig. 71.6.** Noninvasive ventilation (NIV) techniques recruit collapsed alveoli and increase functional residual capacity (FRC), which improves oxygenation and reduces work of breathing (WOB). These factors tend to reduce sympathetic tone, heart rate (HR), and blood pressure (BP), relieving myocardial ischemia. NIV also acts as an afterload-reducing agent, which tends to directly improve cardiac index (CI), systemic oxygen delivery (Do2), partial pressure of oxygen in arterial blood (PaO2), and ventilation-perfusion ratio (V/Q). Preload is also reduced by NIV.

### Vasodilator Agents

#### Nitrates

Organic nitrates activate the enzyme guanylate cyclase, leading to accumulation of cGMP, which relaxes vascular smooth muscle by sequestering calcium in the sarcoplasmic reticulum. At lower doses, nitrates are primarily venodilators. They effectively decrease preload and are therefore very effective in the initial therapy of ACPE. At higher doses, intravenous nitroglycerin also causes arteriolar dilation that decreases BP and afterload. Thus pump function is improved while myocardial oxygen demand is decreased. Nitroglycerin may further reduce myocardial ischemia by its direct coronary vasodilator effect and is particularly effective when myocardial ischemia is contributing to acute decompensation. Prolonged nitrate therapy over hours to days leads to tachyphylaxis secondary to depletion of intracellular sulfhydryl groups.

Nitroglycerin may be initiated by the sublingual route, followed by titrated intravenous administration. Intravenous nitroglycerin has rapid onset and offset of action. Hypotension from excessive preload reduction or vagally mediated idiosyncratic reactions may occur. Nitroglycerin should be avoided in patients who have taken medications for erectile dysfunction (PDE type 5 inhibitors) within the previous 24 hours (up to 48 hours for tadalafil [Cialis]), because the combination may precipitate refractory hypotension. Transcutaneous absorption may be erratic because of diaphoresis and poor skin perfusion, so ointment should not be used as a delivery mechanism until the patient’s condition has stabilized. Sodium nitroprusside works similarly to nitroglycerin, acting as a balanced vasodilator to reduce both preload and afterload. However, patients with renal failure may experience thiocyanate toxicity from high-dose nitroprusside infusions. Cyanide toxicity, recognized clinically by the presence of agitation and lactic acidosis, may occur in individuals with a genetic predisposition. Nitroglycerin also has less hypoperfusion and coronary steal than nitroprusside, and it is the preferred vasodilator in heart failure. Nesiritide, a recombinant human BNP, is not more effective than intravenous nitroglycerin in heart failure. Meta-analyses of studies using nesiritide in acute heart failure suggest no special benefit and the possibility of increased drug-related mortality.107,108 It is not indicated in ED treatment of acute heart failure.

#### Morphine Sulfate

Morphine sulfate, an opioid analgesic, reduces pulmonary congestion through a central sympatholytic effect and release of vasoactive histamine, causing peripheral vasodilation and reduced preload. In addition, through reduced systemic catecholamines, morphine decreases HR, BP, cardiac contractility, and myocardial oxygen consumption. In addition, patients with ACPE tend to be agitated as a result of air hunger, and the calming effect of morphine is advantageous in this setting. Morphine is administered in repetitive 2- to 5-mg intravenous doses carefully titrated to effect. If oversedation results in hypoventilation, gentle stimulation usually restores ventilatory effort. In ACPE, mild carbon dioxide (CO2) retention does not contraindicate morphine use, because it results from acute alveolar flooding that is improved by the mechanisms just delineated. Airway support should be considered, however, before morphine use in obtunded heart failure patients.

#### Loop Diuretics

Loop diuretics inhibit sodium resorption from renal filtrate, resulting in significant increases in salt and water excretion. In
patients with volume overload, this diuretic action lowers plasma volume, decreasing preload and pulmonary congestion. Although the renal effects of intravenously administered loop diuretics begin within 10 minutes, symptom relief in patients with ACPE often occurs much faster, as a result of diuretic-induced neurohumoral changes; acting both as a vasodilator, promoting renal PGE₂ and natriuretic peptide secretion, and as a vasoconstrictor, stimulating renin release. Loop diuretics (furosemide or bumetanide) should be administered to patients with hypertensive ACPE. The half-life of furosemide in patients with ACPE is prolonged when compared to healthy volunteers. Continuous infusion of furosemide is not superior to bolus therapy.¹⁰⁹

Patients with abrupt onset of ACPE who do not have underlying chronic heart failure may have low plasma volumes at presentation, and diuresis in this group of patients may be unnecessary. Patients who fail to respond to loop diuretic administration may have compromised renal function.¹¹⁰ In this situation, invasive hemodynamic monitoring may be beneficial. Diuretic therapy causes depletion of the important cations K⁺ and Mg²⁺, which may be significant in patients already on chronic diuretics or other agents. High-dose diuretic therapy in ACPE is associated with deterioration in renal function and increased mortality.¹¹¹

Other Therapies

Most patients with ACPE and adequate systemic perfusion respond promptly to oxygen with ventilatory support, nitrates, morphine, and diuretics. Hemodialysis may be required in patients with renal insufficiency. Blood transfusion candidates in acute heart failure have worse clinical features but derive some benefit from red blood cell (RBC) repletion for hemoglobin levels below 8 g/dL.¹¹²,¹¹³ The last decade of acute heart failure research for therapies (such as, ET receptor antagonists, vasopressin receptor antagonists, adenosine receptor antagonists, renal natriuretic peptides, calcium-sensitizing drugs, tumor necrosis factor antagonists, and renin inhibitors) has been disappointing.¹¹⁴,¹¹⁵ Early trials of serelaxin, a vasodilating hormone, actually show promise in effectively improving heart failure symptoms, length of hospital stay, and mortality in acute heart failure.¹¹⁶ Historical therapies (eg, rotating tourniquets, phlebotomy, and theophylline) have no demonstrated efficacy in ACPE. Endotracheal intubation should be reconsidered if the patient develops severe respiratory deterioration unresponsive to NIV, significant cardiac dysrythmias, low cardiac output, or has ongoing chest pain.

Treatment of Acute Heart Failure in Hypotensive Patients

Patients with ACPE and apparent systemic hypotension present a therapeutic dilemma. Coronary perfusion in patients depends on the pressure gradient between the aorta and LV chamber in diastole. The combination of hypotension and elevated left-sided filling pressure dramatically decreases coronary perfusion, particularly with coronary artery disease, leading to further impairment of contractility from increased ischemia. Vasopressor administration to maintain coronary perfusion pressure may be necessary if this set of conditions truly exists. Vasopressors, however, can increase afterload, decrease cardiac output, increase myocardial oxygen demand, exacerbate ischemia, and precipitate dysrhythmias. As previously discussed, an intra-arterial catheter provides more accurate and sustained BP monitoring and is helpful in guiding therapy in these patients.

Of patients admitted with heart failure, 15% to 25% have low systolic BP with or without signs or symptoms of hypoperfusion.¹²⁵ If the patient truly has evidence of hypoperfusion, initial measures should be directed at restoring adequate perfusion pressure. In this setting, the patient is either in true cardiogenic shock (pulmonary edema, hypotension, and decreased peripheral perfusion) or is volume depleted. Patients in true cardiogenic shock have lost as much as 40% of their ventricular muscle function. Nearly 25% of patients with acute MI and clinical evidence of systemic hypoperfusion, however, have low preload, indicating the presence of hypovolemia. Fluid challenge alone in these patients restores hemodynamic stability in half. ACPE patients with hypoperfusion might benefit from a judicious fluid challenge, such as a 250-mL crystalloid bolus over 5 to 10 minutes. If respiratory status is not deteriorating, repeated aliquots may be administered. If hypovolemia is contributing to hypotension, this intervention could restore BP and systemic perfusion without need for vaso-pressors. If the patient has true cardiogenic shock, more intensive interventions, including vasopressor therapy, intra-aortic balloon pump, and endotracheal intubation with mechanical ventilation, may be needed.¹²⁶ ACPE with systemic hypoperfusion in the setting of acute coronary syndrome represents ischemic cardiogenic shock. Emergency coronary revascularization is the treatment of choice.¹²⁷

Inotropic or Vasopressor Therapy

Inotropic agent use in heart failure increases myocardial oxygen demand, cardiac arrhythmias, and mortality.¹²⁸ Intravenous inotropic agents with vasoactive properties should be reserved for temporary use in hypoperfused patients with low cardiac output despite a high LV filling pressure.¹²⁹,¹³⁰ In patients with acute MI or ischemia and severe LV dysfunction, the use of a catecholamine may be counterproductive, because all increase myocardial cell work and exacerbate ischemia myocardial cell damage. Revascularization to reperfuse stunned or hibernating myocardium is preferable.

In hypotensive patients who are adequately volume repleted (true cardiogenic shock), norepinephrine is the pressor of choice.¹³¹ It raises BP and coronary perfusion pressure (alpha-vasoconstrictor effect) with a modest beta effect for inotropy, and the least overall increase in HR and contractility, limiting the increase in myocardial oxygen demand. In cardiogenic shock, norepinephrine administration is a temporizing maneuver to maintain coronary perfusion pending rescue strategies, such as angioplasty, intra-aortic balloon pumping, or cardiac surgery.

Dopamine is a naturally occurring catecholamine and a norepinephrine precursor. It has a dose-dependent effect on peripheral vascular tone and is a positive inotropic and chronotropic agent. Despite previous recommendations, dopamine in heart failure has not clinically significant perfusion-sparing effect on the kidneys at any dose.¹³² Epinephrine is a potent alpha- and beta-agonist that maintains BP and increases cardiac output. In cardiac surgery patients, it combats myocardial stunning after cardiopulmonary bypass. Dobutamine is a synthetic catecholamine that is mainly a beta₁-receptor agonist with some beta₂- and alpha-agonist activity. It is an inotropic vasodilator at therapeutic doses and should be used with caution in patients with borderline hypotension, because it occasionally reduces BP further. Isoproterenol is a potent beta-agonist that causes profound tachycardia with vasodilation and is contraindicated in heart failure.

Aminophylline and milrinone are PDE type III inhibitors that increase cyclic adenosine monophosphate (cAMP) in the myocardium and peripheral smooth muscle. These intravenous vasodilating inotropic agents increase cardiac output and reduce LV pressures without producing significant changes in HR and BP. The positive inotropic effects of aminophylline and dobutamine are additive, and concomitant use of both drugs appears to be better tolerated than high doses of dobutamine alone, with lower metabolic consequence. Aminophylline and milrinone may be useful on a short-term basis in patients awaiting heart transplantation. They should be used with caution in selected patients, usually in the
context of invasive hemodynamic monitoring. These agents are prodysrhythmic, and long-term use of PDE type III inhibitors reduces survival in heart failure.125

**Rate and Rhythm Controllers**

Rate and rhythm control is occasionally necessary in heart failure. Compensatory tachycardia is the rule in heart failure, unless the patient is taking beta-blocking agents. Noncompensatory tachycardia increases myocardial oxygen consumption while reducing coronary perfusion and is a particular problem with atrial flutter or fibrillation with rapid ventricular response. Diltiazem is effective and a safe choice in this situation in normotensive patients.144 Various other medical therapies are available in acute atrial fibrillation.135 Electrical cardioversion is indicated when a new-onset tachydysrhythmia is causing or exacerbating heart failure, especially with hypoperfusion or ongoing evidence of myocardial ischemia. Transcutaneous pacing may be necessary in severe bradycardia with hypotension.

**Chronic Heart Failure**

Chronic heart failure involves a more gradual onset of symptoms, with a slow increase in dyspnea on exertion, progressive orthopnea, fatigue, and other symptoms. Patients with chronic heart failure often have complex multiorgan dysfunction, several comorbidities, and use polydrug medical regimens. In this clinical setting, the potential impact of any therapeutic intervention on the entire spectrum of disease and compensatory mechanisms should be considered. For example, adding an NSAID to the medical regimen of a patient with chronic heart failure may negatively affect renovascular function and precipitate increased fluid retention and pulmonary edema.

Neurohormonal modulation is the cornerstone of therapy for chronic HFrEF but is much less effective in HFrEF.136,137 The mainstay of treatment for both chronic heart failure and asymptomatic LV dysfunction is vasodilator therapy, which benefits pump function by reducing both afterload and preload. The most important vasodilators for chronic heart failure are ACE inhibitors, angiotensin II receptor antagonists, and nitrates.

**Common Therapeutic Agents in Chronic Heart Failure**

**Renin Angiotensin System Blocking Drugs.** ACE inhibitors are natriuretic vasodilators that block production of angiotensin II and aldosterone secretion, reducing diuretic and potassium supplement requirements. Additional ACE inhibitor effects include inhibition of bradykinin degradation and reduction of intrinsic ET-dependent vasoconstriction. ACE inhibitors provide the most effective therapy for LV dysfunction, increasing survival in all classes of chronic heart failure, as well as reducing development of heart failure in patients with MI and asymptomatic LV dysfunction.138 Unlike most other vasodilators, they do not induce reflex tachycardia. Main side effects of ACE inhibitors are hypotension, deterioration of renal function, chronic cough, and upper airway angioedema. ACE inhibitors should be initiated at low doses with careful attention to the potential for hypotension, with concomitant reduction in diuretic and potassium supplementation. Optimization of ACE inhibitor dosage appears to be neglected in many patients with heart failure, particularly the elderly.139

Angiotensin type I (AT1) receptor blockers are most useful in patients intolerant of ACE inhibitors, and cause less cough and bradykinin accumulation.140 Both ACE inhibitors and ARBs allowed reverse remodeling in heart failure and reduce risk of development of atrial fibrillation.141,143 ARBs are not superior to ACE inhibitors in reducing mortality or hospitalization for heart failure.144 The combination of an ARB and an ACE inhibitor (dual renin-angiotensin blockade) provides minimal additional benefit, but increases hyperkalemia and hypotension while worsening renal function, and is no longer recommended in heart failure.145

**Beta-Blocker and Combined Alpha- and Beta-Blocker Therapy.** Despite the apparent paradox of using agents that reduce myocardial contractility, beta-adrenergic blocking agents have significant efficacy in chronic heart failure. Long-term activation of the sympathetic nervous system in heart failure, direct cardiotoxicity because of elevated norepinephrine levels, activation of the RAAS, and myocardial beta-adrenergic receptor downregulation are associated with adverse effects.146 An extensive meta-analysis shows that beta-blockers in chronic heart failure significantly increase EF and decrease mortality.147 HR reduction with use of beta-blockers correlates with improvement in LVEF and lowers death rate in heart failure.148 AHA/ACC guidelines recommend beta-blockers for all patients with symptomatic LV systolic dysfunction.149,150

Beta-blockers should not normally be initiated in acute heart failure. They are most useful in chronic heart failure associated with conditions having indications for beta-blocker therapy, including hypertension, angina pectoris, and significant dysrhythmias. Slow upward titration of beta-blocker therapy facilitates maximal tolerability. This is particularly important in COPD, where beta-1 selective agents are effective and preferred in heart failure.141 Usually, it is not necessary to discontinue beta-blocker therapy in the setting of acute decompensation of chronic heart failure, but dose reduction may be appropriate if there is hemodynamic instability.151 Carvedilol, a third-generation alpha- and beta-blocker with vasodilating and antioxidant properties, may be a particularly effective agent in chronic heart failure. Although direct comparisons show carvedilol superior to other beta-blockers in heart failure, the benefits of beta-blockers in HFrEF appears to be mainly a class effect, because no clear evidence supports superiority of any single agent.152-155

**Diuretics.** Patients with chronic heart failure exhibit a reduced ability to excrete a sodium and water load, with abnormal cardiac and hemodynamic adaptations to salt excess.156,157 Low-dose diuretics are used to prevent recurrence of heart failure, but there is limited evidence from randomized trials to guide their use.158,159 Loop diuretics, although commonly used, are associated with significant side effects, including hypovolemia, electrolyte disturbances (low K+, Mg2+, and Na+), hyperuricemia, worsening renal function, and metabolic alkalosis. Torsemide, unlike furosemide, inhibits aldosterone secretion and has other effects that may make it a more effective loop diuretic in chronic heart failure.158 The addition of thiazide diuretic therapy to loop diuretics greatly increases sodium and fluid excretion but increases side effects.159

The hypokalemia and hypomagnesemia secondary to diuretic therapy are prodysrhythmic. The use of potassium-sparing diuretics in heart failure is associated with a reduced risk of death. Spironolactone and eplerenone directly antagonize aldosterone and are equally effective.160 They significantly reduce mortality while improving LV function in patients with severe heart failure (EF below 35%) already being treated with an ACE inhibitor and a loop diuretic, with or without digoxin.161,162 Spironolactone reverses remodeling in patients with mild to moderate chronic systolic heart failure.163 Aldosterone antagonists may lead to serious hyperkalemia in the presence of significant renal insufficiency or in patients taking supplemental potassium.

Hyponatremia is common in heart failure and may be exacerbated by diuretics. Low serum sodium is an independent predictor of mortality, hospitalization for heart failure, and death or rehospitalization, despite clinical and hemodynamic improvements similar to those in patients without hyponatremia.164-165
Nitrates. Nitrate therapy, by virtue of a direct vasodilator effect, improves exercise tolerance in chronic heart failure and offers potential hemodynamic improvement. The main problem with nitrate therapy appears to be rapid drug tolerance, which can be partially addressed by daily nitrate drug-free intervals. Isosorbide used in combination with the arteriolar dilator hydralazine prolongs survival in patients with heart failure but less so than ACE inhibitors. ACE inhibitors, however, are less effective in African Americans. A fixed-dose isosorbide dinitrate/hydralazine regimen is particularly effective in chronic heart failure in African Americans, reducing hospitalization and mortality significantly, with these positive effects sustained over time.

Cardiac Glycosides. The cardiac glycosides inhibit the ATP-dependent sodium/potassium pump in the cell membrane of the cardiac myocyte. This inhibition increases the availability of intracellular calcium to contractile proteins in myocardial cells, with modest positive inotropic effect. Low dose digoxin may be of benefit in chronic heart failure by reducing symptoms and improving quality of life and exercise tolerance. Digoxin reduces the rate of hospitalization in chronic heart failure and lowers mortality when added to an ACE inhibitor and diuretic therapy. Digoxin should be used in low doses for persistently symptomatic heart failure patients whose treatment already includes ACE inhibitors, diuretics, and beta-blocker therapy. Digoxin toxicity is a considerable risk in heart failure, particularly with renal insufficiency, and cardic glycosides have limited efficacy in HFpEF.

Other Considerations in Chronic Heart Failure

Electrical Therapy. ICDs have a substantial mortality advantage over antiarrhythmics in chronic heart failure, particularly in patients with previous MI and low LVEF. Prophylactic placement in appropriate patients undergoing coronary artery bypass grafting (CABG), however, has been found to be ineffective in reducing mortality in the first 6 months after surgery. Although a meta-analysis of ICD therapy continues to show benefit in MI patients with low EF, the economic impact is unclear. Newer subcutaneous ICDs require no venous electrodes, are easily implanted with minimal complications, have efficacy and inappropriate shock rates similar to conventional ICDs, and may be a game changer in treating recurrent malignant arrhythmias.

Patients with severe heart failure and significant LV dysynchrony benefit from atrioventricular sequential pacing. RV apical pacing is often used in chronic heart failure but creates abnormal LV contraction, hypertrophy, and reduced pump function. Cardiac resynchronization therapy (CRT) via LV or biventricular pacing attempts to coordinate the activation of the interventricular septum and left ventricle free wall in heart failure. LV or biventricular pacing allows more physiologic LV contraction, and both are equally effective. CRT improves heart failure symptoms and exercise capacity and can reverse chronic cardiac dilatation. CRT combined with ICD use greatly reduces risk of sudden cardiac death and other cardiac events. Cardiac resynchronization in patients with atrial fibrillation has some efficacy in improving EF, as well as functional outcome, and appears more effective than pharmacologic therapy. CRT also reduces functional mitral regurgitation. Intrathoracic impedance monitoring is available on some devices to continuously monitor hemodynamic status in heart failure. Potential roles for telemonitoring in chronic heart failure are evolving.

Antidysrhythmic Therapy. Seventy percent to 95% of patients with cardiomyopathy and heart failure have frequent premature ventricular beats, and 40% to 80% develop nonsustained ventricular tachycardia with an associated increased risk of sudden death. Amiodarone and classmate dronedarone are useful in acute management of sustained ventricular tachyarrhythmias. Unfortunately, amiodarone and other antidysrhythmic agents have significant toxicities and may be proarrhythmic, and none demonstrates decreased mortality in heart failure. In patients with post-MI LV systolic dysfunction with or without heart failure, amiodarone is associated with increased early and late all-cause cardiovascular mortality. Dronedarone has been found to similarly increase mortality and worsen heart failure in patients with LV systolic dysfunction. ICD therapy is superior to antiarrhythmics in preventing sudden death in selected patients with heart failure.

Atrial fibrillation is a marker of worse prognosis in heart failure, and new atrial fibrillation increases morbidity and mortality in chronic heart failure. In chronic heart failure, amiodarone prevents the development of atrial fibrillation and converts significantly more patients with atrial fibrillation to sinus rhythm. In patients with atrial fibrillation and chronic heart failure, however, medical rhythm control does not reduce the cardiovascular death rate compared with rate control. The role of nonpharmacological strategies like catheter ablation is evolving in atrial fibrillation and heart failure.

Rate control of sinus rhythm is recognized as an avenue for therapeutic intervention in heart failure. In patients with LV dysfunction and stable coronary artery disease, elevated HR above 70 beats/min is associated with higher cardiovascular mortality and admission for MI or heart failure. In particular, for every increase of 5 beats/min above 70 beats/min, there are increases in cardiovascular death, admission for heart failure or MI, and coronary revascularization. Ibivabradine, a selective sinus node inhibitor, demonstrates reduced hospitalization and death rates in chronic heart failure with resting HR over 70 beats/min and EF below 35%.

Calcium Channel Blockers. First-generation calcium channel blockers (verapamil, diltiazem, and nifedipine) do not improve survival in chronic heart failure and may precipitate clinical deterioration. Second-generation dihydropyridines (nicardipine and amlodipine) have more moderate negative inotropic effects. Calcium channel blockers used to treat hypertension increase the incidence of heart failure compared with other regimens. Although used to treat hypertension, angina, and dysrhythmias, benefits may be reduced in patients with associated chronic heart failure. There is no compelling evidence for the use of calcium channel blockers in chronic heart failure, although they may be needed in patients intolerant of beta-blockers, ACE inhibitors, ARBs, and combined nitrates plus hydralazine.

Ultrafiltration and Renal Dialysis. Ultrafiltration reduces volume overload when diuretic therapy is inadequate. In decompensated heart failure, ultrafiltration may be more effective than intravenous diuretics in volume overloaded states but does not reduce rehospitalization rate or mortality. Renal dialysis is important for heart failure treatment in end-stage renal disease. Potential complications of renal disease that may need special consideration include fluid overload, severe hyperkalemia, iatrogenic hypermagnesemia, uremic pericardial effusion, and drug toxicity (eg, digitalis). Missed or inadequate dialysis is a frequent cause of chronic heart failure decompensation.

Coronary Artery Bypass Grafting and Angioplasty. In patients with coronary artery disease amenable to CABG and EF below 35%, CABG combined with medical therapy, compared with medical therapy alone, reduces death from cardiovascular causes but not all-cause mortality. Another study shows vessel opening gave no advantage in preventing heart failure, death, or reinfarction in stable patients with occlusion of the infarct-related
artery 3 to 28 days after MI. Assessing for myocardial viability in ischemic LV dysfunction does not identify a survival benefit from CABG. However, early revascularization in non-ST elevation acute coronary syndrome and heart failure reduces mortality.

**Phosphodiesterase Inhibitors.** There are limited indications for use of long-term PDE type 3 inhibitors (amrinone or milrinone), which increase morbidity and mortality in patients with severe chronic heart failure. Use should be limited to hypoperfusion states unresponsive to other therapies. PDE type 5 inhibition with sildenafil, used commonly for erectile dysfunction, is safe in heart failure, and may have other beneficial effects, including better cardiac output and exercise capacity. Long-term use of sildenafil in chronic heart failure and severe pulmonary hypertension improves hemodynamic and clinical status.

**Statins and Polyunsaturated Fatty Acids.** Statins improve endothelial function and have antiinflammatory, antioxidative, and immunomodulatory effects that may be beneficial in patients with chronic heart failure. Early use of statin therapy after acute MI reduces risk of heart failure. Use in nonischemic heart failure improves LVEF and NYHA classification and reduces serum levels of multiple inflammatory markers. A statin reduces risk of heart failure substantially in high-risk populations and also decreases risk of major vascular effects. Statin therapy lowers hospitalizations, reduces inflammatory markers, improves EF, and decreases mortality among patients with severe heart failure.

Utility in mild heart failure is less obvious. High-dose statin therapy adds benefit to lower doses in heart failure. Omega-3 polyunsaturated fatty acids show improved LV systolic function, functional capacity, and reduced hospitalizations in patients with dilated cardiomyopathy. In patients with heart failure from any cause, omega-3 polyunsaturated fatty acids use leads to a small decrease in mortality and admissions for cardiovascular reasons. The Mediterranean-style diet, with a focus on vegetables, fruit, fish, whole grains and olive oil, is particularly effective in reducing cardiovascular events, including heart failure.

**Anemia.** Anemia is present in about one-third of chronic heart failure patients and is associated with increased mortality in both systolic and diastolic heart failure. Iron deficiency occurs with a similar frequency in heart failure. Improving anemia in chronic heart failure by using iron supplements improves LV systolic function, LV remodeling, BNP levels, NYHA class, sleep-related breathing disorders, and renal function, as well as need for hospitalization. A higher transfusion threshold does not seem helpful in heart failure, whereas erythropoiesis-stimulating agents can provide clinical benefits, but may cause harm.

**Sleep Apnea-Related Respiratory Support.** Hypoxemia and related hemodynamic stress underlies the impact of sleep disorders in heart failure. Obstructive sleep apnea is more prevalent in chronic heart failure than previously recognized, and treatment improves nocturnal oxygenation, EF, and exercise capacity, but is not proven to increase survival. Effective treatments for obstructive sleep apnea include CPAP, BiPAP, and adaptive servventilation, with the latter most effective and involving variable ventilatory pressure support synchronization based on respiratory rate and airflow. Other therapies include dental devices, surgery, and weight loss.

**Exercise Programs.** Cardiopulmonary exercise testing provides prognostic information in patients with heart failure. Various exercise programs in chronic heart failure show benefits in terms of functional status and quality of life, and reduce rehospitalization rates, but do not reduce mortality.

**Advanced Surgical Therapies.** Management of severe left-sided valvular failure, when appropriately timed, may be very helpful in both preventing and treating heart failure. Transcatheter valve replacement is developing as an effective, minimally invasive surgical technique.

After a promising beginning, left ventriculoplasty has largely been abandoned because of failure to demonstrate long-term efficacy in heart failure. A study of ventriculoplasty during coronary artery bypass surgery also failed to show functional improvement or reduced mortality in heart failure.

In contrast, LV aneurysm repair is useful in severe heart failure.

Multiple implantable left ventricular assist devices (LVADs) are in use for chronic heart failure as a bridge to transplantation and as a surgical alternative to chronic medical management. Treatment of end-stage heart failure with LVADs has been shown to improve cardiorespiratory performance during exercise testing, as well as overall quality of life. LVAD technology has advanced greatly, and there is potential for this as a long-term alternative to transplantation. Familiarity with proper LVAD function and potential complications is a new arena of learning for emergency clinicians.

Heart transplantation is still the most effective therapy for end-stage heart failure, with median survival exceeding 10 years. The limited availability of donors (2500 heart transplants per year in the United States) and need for lifelong immunosuppression makes alternative surgical techniques of interest in end-stage heart failure. There is increasing evidence that stem cell therapy may offer promise in chronic heart failure, but it remains at the research level at present.

Autologous stem cell transplantation significantly improved cardiac function in a small number of patients undergoing CABG for ischemic cardiomyopathy. However, multiple challenges need to be overcome before stem cell therapy can advance beyond the experimental level for heart failure therapy.

**Psychosocial Factors.** Significant depression is common in patients with heart failure and increases cardiovascular mortality. Treatment is challenging, but exercise programs, improved social support, and appropriate pharmacotherapy are helpful.

A discussion of end-of-life preferences and palliative care is important in advanced heart failure. Hospice services may be particularly useful in that setting.

**DISPOSITION**

**Admission Criteria, Observation Units, and Predictors of Readmission**

Appropriate disposition of patients presenting with decompensated heart failure depends upon clinical stability, comorbidities, precipitating events, and the availability of resources that may determine hospital admission versus an alternate pathway. In general, exacerbations of chronic heart failure need admission if the cause of the exacerbation cannot be readily recognized and corrected, if the disease process is unstable, or if clinical deterioration appears likely. Precipitating events, including acute coronary syndrome, concomitant pneumonia, or worsening renal function increase hospital mortality and should prompt admission. Additionally, several risk factors predict poor post-discharge outcome, including ischemic ECG changes, elevated troponin or natriuretic peptide levels, hyponatremia, elevated blood urea nitrogen (BUN) or creatinine, and low systolic BP. In-hospital mortality for acute decompensated heart failure is about 4%, but higher with increased age, elevated HR, hyponatremia, hypotension, LV...
systolic dysfunction, increased BUN, creatinine, troponin, or natriuretic peptides, or if heart failure is the primary cause for admission.\textsuperscript{261-262}

In comparison, patients presenting to the ED with rectifiable dietary or medication noncompliance issues may be safely discharged with close follow-up. However, many of these patients are admitted because of the inability to identify those at low risk for poor outpatient outcomes, or difficulty providing proper bedside heart failure education and close follow-up. In fact, re-hospitalization occurs at higher rates when patients are directly discharged from the ED.\textsuperscript{263} Observation units may have a substantial role in avoiding heart failure admission, reducing costs, and providing a bridge to appropriate outpatient care.\textsuperscript{264-265} Reporting of preventable readmissions, changing financial incentives, and an emphasis on education and post-discharge care help drive the discussion of short-stay observation units for patients with heart failure. Evidence suggests that certain patients need only minimal therapies.\textsuperscript{266-267} The question remains if low risk patients that quickly respond to therapy can be safely discharged after observation with close outpatient follow-up.\textsuperscript{266} More evidence is needed to determine which heart failure patients may benefit from observation units.

The difficulties of outpatient heart failure management range from compliance and understanding of the multifactorial therapeutic strategies to optimization of care after hospital discharge, including diet, medications, and weight monitoring. Patients with heart failure are frequently readmitted for both cardiac and unrelated causes.\textsuperscript{269} Several studies have demonstrated reduced readmission rates with individualized, comprehensive discharge planning, structured post-discharge follow-up, telemonitoring, and directed home self-management.\textsuperscript{270-275} Readmission rates are lower for those with comprehensive discharge planning and post-discharge support versus standard therapy.\textsuperscript{270-275} There is significant variability in the adherence to heart failure quality-of-care issues in the United States. Prompt initiation of optimal therapeutic modalities leads to early benefits, including decreased risks of mortality and rehospitalization for heart failure.\textsuperscript{276}

**KEY CONCEPTS**

- Heart failure is among the most frequent conditions resulting in emergency department (ED) visits and hospital admissions, with high morbidity and mortality.
- Heart failure can be divided into heart failure with preserved ejection fraction (HFrEF) and heart failure with reduced ejection fraction (HfReEF), which have similar incidences, morbidities, and mortalities, but different pathophysiologies and response to therapies.
- Neurohormonal mechanisms provide initial compensation for cardiac dysfunction but are ultimately deleterious in heart failure. Chronic therapy to negate these effects is important even in asymptomatic myocardial dysfunction.
- The most common manifestation of acute heart failure is respiratory distress, triggering a differential diagnosis primarily including non-cardiogenic pulmonary edema, exacerbation of chronic obstructive pulmonary disease (COPD) or asthma, pulmonary embolus, pneumonia, tension pneumothorax, cardiac tamponade, and anaphylaxis.
- Recognition of precipitating causes in heart failure allows early understanding of appropriate management issues.
- Biomarkers such as B-type natriuretic peptide (BNP) may improve recognition of heart failure in dyspnea of unclear cause, correlate with severity, help stratify risk, and monitor therapeutic response.
- Distinguishing primary pulmonary disease causing predominantly right-sided heart failure from left ventricular (LV) failure with secondary right-sided dysfunction is clinically challenging, because the physical examination findings and chest radiograph may be similar. Natriuretic peptide levels are much higher in LV failure.
- Most acute heart failure can be managed with upright positioning, supplemental oxygen, non-invasive ventilation, vasodilators, and loop diuretics.
- Hypoperfusing patients with acute cardiogenic pulmonary edema (ACPE) often have unreliable cuff blood pressure (BP) readings and may benefit from invasive arterial monitoring.
- Patients with true poor perfusion may benefit from fluid challenge to restore preload, cardiac output, systemic perfusion, and BP. Careful volume infusion with aliquots of normal saline is appropriate initial resuscitation for the hypoperfusing patient with acute-onset cardiogenic pulmonary edema.
- In hypoperfusing patients who are adequately volume repleted (true cardiogenic shock), norepinephrine is the pressor of choice.
- In chronic heart failure, routine use of beta-blockers, angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs), diuretics including spironolactone, and occasionally digoxin has resulted in sustained symptomatic improvement and reduced 5-year mortality in HFrEF.
- Various electrical therapies, particularly cardiac resynchronization therapy (CRT) and implantable defibrillators, as well as mechanical techniques like implantable left ventricular assist devices (LVADs) and cardiac transplantation add complexity to chronic heart failure management, but improve morbidity and mortality.
- Observation medicine plays an increasing role in reducing costs and admissions in heart failure.

PART III

71.1. In developed countries, what is the most common cause of heart failure?
   A. Acute myocarditis
   B. Atherosclerotic coronary artery disease
   C. Chronic obstructive pulmonary disease (COPD)
   D. Dilated cardiomyopathy
   E. Valvular heart disease

Answer: B. In developed countries, atherosclerotic coronary artery disease is the leading cause of heart failure, present in almost 70% of patients in multicenter heart failure trials. Dilated cardiomyopathy is much more common than hypertrophic or restrictive types and is the second most common cause of heart failure. Valvular heart diseases and myocarditis are less common causes of heart failure. COPD, with a prevalence of 20% to 30% in heart failure, frequently obscures its recognition.

71.2. A 54-year-old male with a history of hypertension and diabetes mellitus presents with sudden onset of dyspnea and severe chest pain. His electrocardiogram (ECG) shows 2 to 3 mm of ST-segment elevation in leads V1 to V4. A portable chest radiograph demonstrates evidence of pulmonary edema. He is placed on oxygen and a nitroglycerin drip, and his chest pain resolves while his ECG changes improve. His blood pressure (BP) suddenly drops to 80/54 and his heart rate (HR) increases to 112 beats per minute. Besides stopping the nitroglycerin drip and contacting interventional cardiology, what is the next appropriate therapeutic intervention?
   A. Crystallloid boluses to restore perfusion
   B. Intra-arterial pressure monitoring to confirm hypotension
   C. Lopressor to reduce HR
   D. Norepinephrine for cardiogenic shock
   E. Thrombolytic therapy for ST-elevation myocardial infarction (STEMI)

Answer: A. Understanding the pathophysiology here is important. Presumably, this is acute coronary syndrome, probably resulting from left anterior descending coronary artery occlusion. The resultant acute diastolic dysfunction increases left ventricular (LV) filling pressure greatly and leads to flash pulmonary edema with alveolar flooding. This pulmonary edema came from acute displacement of intravascular volume, which is now significantly reduced. Because coronary ischemia often has a stuttering course and nitroglycerin may also improve coronary perfusion through vasodilatory properties, the ischemia and diastolic dysfunction can acutely resolve. Hypotension, if it occurs, is related to intravascular volume depletion, and crystallloid volume replacement, done judiciously, is the most appropriate intervention. Lopressor, a beta-blocking agent, would be less helpful here, because cardiac inotropic function needs to be maintained. Norepinephrine is the vasopressor of choice for cardiogenic shock, but in this particular setting, volume resuscitation should be tried first. Although intra-arterial pressure monitoring is appropriate to best understand the true perfusion situation, volume resuscitation is needed promptly. Percutaneous coronary intervention has a survival advantage over thrombolytic therapy in cardiogenic shock resulting from acute myocardial infarction (AMI). With resolution of myocardial ischemia and related improvement in cardiac function, the pulmonary edema will eventually return to the intravascular space. Noninvasive ventilation (NIV) may accelerate this process.

71.3. Which of the following is not a common precipitating factor for heart failure?
   A. Acute atrial fibrillation
   B. Acute hypertension

Answer: C. Adrenal insufficiency
D. Iatrogenic volume overload
E. Pneumonia

Answer: C. Infection, particularly pneumonia resulting from its associated hypoxia and increased work of breathing, is a common precipitating factor for heart failure. Acute atrial fibrillation may reduce ventricular priming (a particular problem with diastolic dysfunction) and also increase heart rate (HR), contributing to heart failure. Volume overload, either because of dietary noncompliance or excessive crystalloid infusion during patient care, can rapidly cause heart failure. Uncontrolled blood pressure (BP) elevations, often resulting from medication noncompliance, may contribute to heart failure exacerbations. Adrenal insufficiency is associated with intravascular volume depletion and more likely to cause hypoperfusion.

71.4. A 63-year-old male presents with an acute exacerbation of chronic heart failure. He admits to moderate alcohol and occasional cocaine use. He is presently intoxicated and slightly agitated. His blood pressure (BP) is 234/124 mm Hg with a heart rate (HR) of 128, respiratory rate of 28, and temperature at 100.4°F (38.0°C), along with oxygen saturation measured by pulse oximetry (SpO2) of 95% on room air. He has jugular venous distention; bibasilar rales; a rapid, regular S1 and S2; and 3+ edema in both lower extremities. Which of the following interventions is likely to provide the most benefit?
   A. 100% oxygen by face mask
   B. Biphasic positive airway pressure (BiPAP)
   C. Furosemide
   D. Lopressor
   E. Nitroglycerin

Answer: E. Lopressor, a beta-blocking agent, is not usually a drug of choice in acute heart failure and may indeed lead to unopposed alpha-agonist effect if cocaine has been recently used, with possible deterioration. The patient’s pulse oximetry suggests adequate oxygenation, and supplemental oxygen would provide minimal benefit, whereas hypoxemia may theoretically increase afterload by its vasoconstrictive effect. Similarly, noninvasive ventilatory support using BiPAP may not be well tolerated in this agitated patient, and although it may help by reducing both preload and afterload, better options exist. Furosemide may be a reasonable intervention, but prompt afterload reduction with nitroglycerin, preferably intravenously, is likely to be the most beneficial treatment for this very hypertensive heart failure patient.

71.5. Each of the following classes of medications has a significant role in the management of chronic heart failure, except:
   A. Angiotensin-converting enzyme (ACE) inhibitors
   B. Beta-blockers
   C. Calcium channel blockers
   D. Diuretics
   E. Nitrates

Answer: C. Beta-blocker therapy increases survival in heart failure, probably through modulation of multiple neurohormonal responses. ACE inhibitors provide the most effective therapy for left ventricular (LV) dysfunction. Diuretics help deal with the decreased ability to excrete excess salt and water in heart failure. Nitrates, by direct vasodilatory effects, improve exercise tolerance and hemodynamics in chronic heart failure. Calcium channel blockers, particularly first-generation ones (verapamil, diltiazem, and nifedipine), do not improve survival in this disease, and there
is no compelling evidence that they are useful in chronic heart failure.

71.6. A 47-year-old female presents with severe shortness of breath and palpitations. She has bilateral proptosis; a symmetrically enlarged thyroid gland; inspiratory crackles bilaterally on pulmonary examination; rapid, irregular heart sounds on cardiac examination; and bipedal edema. Her blood pressure (BP) is 220/100 mm Hg with an irregular pulse at 156 beats per minute. What is the initial therapy of choice?

A. Dexamethasone  
B. Diltiazem  
C. Esmolol  
D. Nesiritide  
E. Nitroglycerin

Answer: C. This patient has acute pulmonary edema and probable atrial fibrillation, with a high output type of heart failure likely due to thyrotoxicosis, presumably caused by Graves' disease. Beta-blockade, here with esmolol, which has a short half-life and can be titrated, is in this particular clinical situation the therapy of choice among these options. Beta-blockade will reduce the elevated thyroid hormone effects on cardiac function, which probably precipitated high output heart failure and atrial fibrillation. Vasodilator therapy with nitroglycerin will not improve the cardiac effects of thyrotoxicosis, and nesiritide has minimal role in the present treatment of heart failure. Diltiazem may reduce ventricular rate but is not the most effective treatment in this clinical situation. Dexamethasone plays a minor role in the treatment of thyrotoxicosis.
Pericardial and Myocardial Disease

Nicholas J. Jouriles

CHAPTER 72

PERICARDIAL DISEASE (PERICARDITIS)

Principles

Pericardial Anatomy Physiology and Pathophysiology

The pericardium envelops the heart and attaches to the great vessels. It consists of parietal and visceral layers, with a narrow potential space between. Each layer is 1 or 2 mm thick and is composed of elastic fibers. Its blood supply comes from the internal mammary artery; its nerve supply comes from the phrenic nerve. An ultrafiltrate of plasma, 15 to 35 mL of fluid, is normally contained in the pericardial space. The pericardium serves several functions: It maintains the heart’s position, lubricates the heart’s surface, prevents the spread of infection, prevents cardiac overdistention, augments atrial filling, and maintains the normal pressure-volume relationships of the cardiac chambers. Patients with congenital absence (or surgical removal) of the pericardium, however, show few, if any, problems. Pericardial absence may be associated with other, genetic based problems.

The inflammation of pericarditis is characterized by a granulocytic and lymphocytic infiltration of the pericardium. There is an increase in the number of antibodies in the pericardial fluid.

SPECIFIC DISORDERS: IDIOPATHIC PERICARDITIS

Principles and Clinical Features

The classic symptoms of pericarditis include chest pain, pericardial friction rub, and electrocardiogram (ECG) abnormalities. A history of fever and myalgias is common. Pericarditis chest pain is sharp, pleuritic, and varies with position. It is relieved by sitting forward and worsened by lying down, deep inspiration, or swallowing. Pericarditis pain is retrosternal, can radiate to the trapezius muscles, or can present as isolated shoulder pain.

The classic physical examination finding is a pericardial friction rub. The rub may be caused by friction between inflamed or scarred visceral and parietal pericardium or may result from friction between the parietal pericardium and adjacent pleura. It may be audible anywhere over the anterior chest wall and is best heard with the stethoscope diaphragm positioned at the lower left sternal border with the patient leaning forward in full expiration. The rub also can be accentuated by a full inspiration, followed by a breath hold. The rub tends to be intermittent, migratory, and difficult to hear in a loud emergency department (ED).

Differential Diagnosis

In patients with pericardial disease, the differential diagnosis would include inflammatory or infectious disease of the chest wall (costochondritis), pleura (pleurisy or pleuritis), or other infections, such as pneumonia. Rarely pulmonary embolism can mimic pericarditis and must be considered in the differential diagnosis and ruled out based on history, physical findings, risk stratification, and diagnostic testing.

Acute coronary syndromes may also mimic pericarditis; and a thorough history and physical examination, as well as diagnostic testing, rarely only consultation with cardiology and/or coronary angiography can distinguish these entities.

Diagnostic Testing

There is no single test that is diagnostic for pericarditis. The ECG is the most reliable diagnostic tool. It evolves through stages over time. The first stage occurs in the first hours to days of illness and includes diffuse ST segment elevation and reciprocal ST segment depression. Most patients with acute pericarditis have concurrent PR segment depression (Fig. 72.1). In the next stages, the ST and PR segments normalize, but the T waves flatten followed by deep, symmetrical T wave inversion. At the last stage, the ECG reverts to normal, although the T wave inversions may become permanent.

The classic chest pain and ECG patterns are seen in only two-thirds of patients with pericarditis, making the diagnosis difficult.

The early ECG findings of acute pericarditis may be difficult to distinguish from acute myocardial infarction (AMI), coronary artery spasm, or benign early repolarization. In contrast to the ECG in AMI, the ST segment elevations in stage 1 acute pericarditis are concave rather than convex upward, simultaneous T wave inversions are not seen, and the findings are not bound to a single coronary artery distribution. Subsequent tracings do not evolve through a typical myocardial infarction (MI) pattern, and Q waves do not appear. When the ECG pattern suggests acute coronary syndrome and the pain is not clearly pericardial in nature, the best course after observation is diagnostic coronary angiography. Ventricular dysrhythmias are rare in pericardial disease. Patients with pericarditis who have ventricular dysrhythmias should be presumed to have concomitant myocarditis, another cardiac disease, or to have been misdiagnosed.

Echocardiography facilitates the definitive diagnosis of pericarditis with effusion. A normal echocardiogram does not exclude pericarditis. Cardiac tamponade, increased pericardial thickness, pericardial tumors, cysts, constrictive pericarditis, and the congenital absence of the pericardium can all be diagnosed by echocardiography.

Some patients with acute pericarditis have elevated cardiac markers caused by myocarditis, myocarditis, or MI. The white blood cell (WBC) count and erythrocyte sedimentation rate (ESR) may be elevated or normal and are not sensitive or specific. Other laboratory studies should be directed at determining non-idiopathic causes of pericarditis.

It is at times difficult to distinguish acute coronary syndrome from pericarditis. In those cases, acute coronary syndrome should be ruled out.

Management and Disposition

If a specific etiology of pericarditis is found, therapy should be directed at that cause. Otherwise, therapy for acute pericarditis is
UREMIC PERICARDIAL DISEASE

Principles

Uremic pericarditis occurs secondary to renal failure or dialysis. The etiology of dialysis-associated pericarditis is unknown and may be associated with both hemodialysis and peritoneal dialysis; although for unclear reasons, it occurs more frequently with hemodialysis. Uremic pericarditis is associated with occult infection and the evaluation of a chronic renal disease patient with pericarditis requires a diligent search for infectious causes.

Clinical Features and Diagnostic Testing

Patients with uremic pericarditis have typical symptoms and physical examination findings. The ECG in uremic pericarditis is often normal because little epicardial inflammation occurs. In a dialysis patient, cardiac enlargement on chest radiograph in the

symptomatic. Nonsteroidal antiinflammatory drugs (NSAIDs) are the first choice. The patient will often report significant pain relief from the analgesic effect even before onset of the antiinflammatory effect. Ibuprofen has the best side effect profile, but other NSAIDs are equally effective. If the chosen NSAID is not effective within 1 week, a different class of NSAIDs should be tried. Colchicine should be added to reduce the risk of recurrent pericarditis. Colchicine is also the treatment of choice for recurrent pericarditis, where steroid therapy has shown mixed results. Recurrent pericarditis is often due to an immune or rheumatologic etiology, and surgery is an option if medical therapy fails. Most patients can be managed as an outpatient unless significant pericardial effusion, diagnostic uncertainty with acute coronary syndrome, or patient has hemodynamic abnormalities that preclude outpatient management (Box 72.1).

Complications

The clinical course of pericarditis is variable: 60% of patients have complete recovery within 1 week, and almost 80% have complete recovery within 3 weeks. Patients with fever, pericardial effusion, a subacute course, or failure of initial NSAID treatment have a worse prognosis. Eighteen percent of patients will have recurrent pericarditis that requires serial echocardiography to exclude effusion or tumor.
Postinjury Pericarditis

Principles

Postcardiac injury syndrome is defined as pericarditis after MI, cardiac surgery, or trauma. The incidence ranges from approximately 5% after MI to 30% after thoracic surgery or trauma. It can also occur after chest trauma that does not involve the heart or pericardium.

Injury to the pericardium in blunt trauma may range from contusion to laceration or rupture. Some degree of traumatic pericarditis is found during surgery or at autopsy in many patients sustaining severe blunt trauma of the chest. Penetrating wounds to the heart usually cause laceration of the pericardium and the myocardium, with secondary pericarditis and pericardial infections. Although the exact incidence is unknown, infection, tamponade, myocarditis, and inflammatory pericarditis may occur. An immune pathogenesis is suggested by the development of cardiac autoantibodies, although these autoantibodies are common after injury, even in patients who do not develop pericarditis.

Clinical Features, Diagnostic Testing, Management, and Disposition

Symptoms and signs of postcardiac injury syndrome include pericardial rub, fever, and chest pain. Although the diagnosis is usually established clinically, confirmation by echocardiography is helpful. The interval between injury and the onset of pericarditis ranges from 4 to 12 days. During hospitalization, purulent pericarditis should be considered as a possible source of febrile illness in a trauma patient with multisystem organ failure.

Most patients respond to aspirin or NSAIDs. Uncomplicated pericarditis secondary to blunt trauma usually resolves.

Neoplastic Pericardial Disease

Principles

Malignant pericardial tumors typically manifest late, which complicates diagnosis and treatment. Malignant involvement of the pericardium is observed in up to 31% of cancer autopsies. The most common associated cancers are lung (30%), breast (23%), lymphoma (17%), and leukemia (9%). Primary malignancies of the pericardium are rare.

The pattern of cardiac involvement by a malignant tumor is determined by the heart’s lymphatic drainage system. Malignant pericardial effusions contribute directly to the patient’s death—in most cases from cardiac tamponade. Although the underlying disease process is often advanced when tamponade develops, the patient’s quality of life can usually be improved if tamponade is treated promptly.

Clinical Features and Diagnostic Strategies

Primary cardiac neoplasms initially cause symptoms consistent with pericarditis. The typical course is that of an acute pericarditis that resolves then recurs. Malignant pericardial disease is difficult to diagnose. Most patients are asymptomatic or have nonspecific symptoms, such as shortness of breath, cough, palpitations, ill-defined chest pain, weakness, dizziness, hiccup, or fatigue.

The diagnostic evaluation includes an echocardiogram, computed tomography (CT), or magnetic resonance imaging (MRI). Pericardial fluid cytology is recommended if the underlying malignancy is undiagnosed.

Approximately 20% of patients with transmural MI experience a different quality of chest pain 2 to 4 days after infarction. This pain may represent early post-MI pericarditis. There is frequently low-grade fever and a transient pericardial friction rub. Early post-MI pericarditis is generally short-lived and is treated with aspirin therapy. The ECG changes of pericarditis usually are masked by the AMI changes, making the diagnosis difficult. Patients with early post-MI pericarditis have more dysrhythmias and heart failure. Pericarditis in AMI may be an indicator of greater myocardial damage and a worse outcome.

In contrast to early post-MI pericarditis, Dressler reported a syndrome of fever, pleuritis, leukocytosis, friction rub, and chest radiograph evidence of new pericardial or pleural effusions in post-MI patients. Frequent relapses led Dressler to describe this syndrome as a delayed complication of MI. The cause of late post-MI pericarditis (Dressler’s syndrome) may be immunologic. The syndrome may also occur with pulmonary embolus and after pericardiectomy. Anticoagulants should be discontinued to reduce the risk of hemorrhage. Delayed post-MI pericarditis is treated with NSAIDs.

Absence of signs of volume overload or congestive heart failure (CHF) should prompt consideration of pericardial effusion. Ultrasound will provide the definitive answer. Uremic pericarditis is one of the most common causes of cardiac tamponade.

Management and Disposition

Uremic pericarditis is initially treated with intensive dialysis. NSAIDs are ineffective and often are contraindicated. Systemic steroids should be used in the few patients who do not respond to dialysis.

**Post–Myocardial Infarction Pericarditis**

Approximately 20% of patients with transmural MI experience a different quality of chest pain 2 to 4 days after infarction. This pain may represent early post-MI pericarditis. There is frequently low-grade fever and a transient pericardial friction rub. Early post-MI pericarditis is generally short-lived and is treated with aspirin therapy. The ECG changes of pericarditis usually are masked by the AMI changes, making the diagnosis difficult. Patients with early post-MI pericarditis have more dysrhythmias and heart failure. Pericarditis in AMI may be an indicator of greater myocardial damage and a worse outcome.

In contrast to early post-MI pericarditis, Dressler reported a syndrome of fever, pleuritis, leukocytosis, friction rub, and chest radiograph evidence of new pericardial or pleural effusions in post-MI patients. Frequent relapses led Dressler to describe this syndrome as a delayed complication of MI. The cause of late post-MI pericarditis (Dressler’s syndrome) may be immunologic. The syndrome may also occur with pulmonary embolus and after pericardiectomy. Anticoagulants should be discontinued to reduce the risk of hemorrhage. Delayed post-MI pericarditis is treated with NSAIDs.

Primary cardiac neoplasms initially cause symptoms consistent with pericarditis. The typical course is that of an acute pericarditis that resolves then recurs. Malignant pericardial disease is difficult to diagnose. Most patients are asymptomatic or have nonspecific symptoms, such as shortness of breath, cough, palpitations, ill-defined chest pain, weakness, dizziness, hiccup, or fatigue.

The diagnostic evaluation includes an echocardiogram, computed tomography (CT), or magnetic resonance imaging (MRI). Pericardial fluid cytology is recommended if the underlying malignancy is undiagnosed.
Management and Disposition

Tuberculous pericarditis is estimated to occur in 1% or 2% of patients with pulmonary tuberculosis and is associated with high mortality. In Africa, it is the most common cause of pericarditis. Pericardial fluid aspirates reveal acid-fast bacilli by smear or culture (which may require 4 to 6 weeks to become positive) in approximately 50% of cases. Diagnostic evaluation should include assessment for human immunodeficiency virus (HIV). Triple-drug therapy should be started and continued for at least 9 months. Patients do not benefit from oral prednisolone therapy.

OTHER CAUSES OF PERICARDITIS

Amyloid deposition can cause either restrictive cardiomyopathy (RCM) or constrictive pericarditis. Pericarditis can occur rarely as an extra-intestinal complication of inflammatory bowel disease and is independent of the clinical course of the gut disorder. Iatrogenic pericarditis can also occur as a complication of an implantable defibrillator or pacemaker. Bacterial pericarditis can occur after transbronchial needle aspiration or as a complication of endoscopic variceal sclerotherapy. Rarely, pericarditis can also be caused by erosion of a foreign body, such as a sewing needle or toothpick, through the esophagus into the pericardium. Less than 1% of patients with HIV develop acute pericarditis, but 40% have asymptomatic pericardial effusion. This is more frequent in patients in the more advanced stages of HIV infection.

PERICARDIAL EFFUSION

Principles and Clinical Features

The most common causes of pericardial effusion are viral or idiopathic pericarditis, malignancy, uremia, trauma, and radiation therapy. Drug reactions and autoimmune diseases are less common.

Pericardial effusion is often asymptomatic. Patients with known associated conditions (eg, cancer or renal failure) with cough, fever, chest pain, or dyspnea should be considered to have an effusion until proven otherwise.

Diagnostic Testing

A minimum of 200 to 250 mL of pericardial fluid is necessary to produce cardiomegaly on a chest radiograph. Ultrasound is the diagnostic modality of choice (Fig. 72.2). It easily differentiates pericardial fluid from cardiac chamber enlargement and provides information about myocardial wall motion. CT or MRI may be useful when the echocardiogram is technically unsatisfactory. Nuclear scans may be useful to detect purulent pericardial effusions.

Management and Disposition

Pericardiocentesis may be performed for either diagnostic or therapeutic purposes. Common complications include dysrhythmias, pneumothorax, myocardial perforation, coronary or internal mammary artery laceration, and liver laceration. Ultrasound-guided pericardiocentesis is the procedure of choice. Patients requiring pericardial aspiration with pericardiocentesis should be admitted to observation unit or to the hospital for serial examinations and determination of the cause of the pericardial effusion.

CARDIAC TAMPOONADE

Principles

Ten percent of all patients with cancer develop cardiac tamponade. Cardiac tamponade should be suspected in patients with penetrating chest wounds. It is also common in patients with uremic pericarditis.

Cardiac tamponade is the result of compression of the myocardium by the contents of the pericardium. This compression is usually caused by fluid. It may be caused by gas, pus, blood, or a combination of substances.

Cardiac tamponade occurs in a physiologic continuum reflecting the amount of fluid, the rate of accumulation, and the nature of the heart. The most important factor in the development of tamponade is the rate of fluid accumulation. The three stages...
necessary for tamponade to develop are (1) fluid filling the recesses of the parietal pericardium, (2) fluid accumulating faster than the rate of the parietal pericardium’s ability to stretch, and (3) fluid accumulation that exceeds the body’s ability to increase blood volume to support right ventricle filling pressure. The result is increased pericardial pressure, which causes decreased ventricle compliance and decreased flow of blood into the heart. The reduction of blood inflow into the right ventricle results in decreased stroke volume that leads to decreased cardiac output.

The heart initially responds to tamponade by increasing heart rate to maintain cardiac output. This compensatory mechanism is maintained until late in the clinical course, followed by rapid decompensation.

Clinical Features and Diagnostic Testing

Cardiac tamponade symptoms, though often nonspecific, include chest pain, cough, or dyspnea, any of which may be progressive and severe. Dyspnea is the most common. The classic triad described by Beck is hypotension, distended neck veins, and muffled heart sounds. These signs may not be present if tamponade develops quickly.

The chest radiograph may show cardiomegaly but only if there is a large accumulation of fluid (250 mL). The ECG classically shows decreased voltage or electrical alternans (Fig. 72.3). The latter is rare. Ultrasound confirms the diagnosis when effusion and chamber collapse are seen. Cardiac catheterization demonstrates equalization of right and left ventricle pressures.

Management and Disposition

Initial treatment is intravenous fluids to increase right sided filling pressure to overcome pericardial constriction. Pericardiocentesis or pericardial window is the treatment of choice. If tamponade recurs, pericardiocentesis may be repeated, or a drainage catheter may be left in the pericardial space. A pericardiectomy ultimately may be necessary. Cardiac tamponade has a high mortality depending on the severity and nature of the underlying disease, the time course of onset, and the rapidity of diagnosis and
fourtunately. All patients with cardiac tamponade require inpa-

tient management in an intensive care unit (ICU) setting.

**PURULENT PERICARDITIS**

**Principles**

Purulent pericarditis is a life-threatening process most commonly seen in a hospitalized patient with systemic illnesses who develops sepsis. It can occur in any age group and can be caused by any type of infectious agent. *Streptococcus* and *Staphylococcus* are the most common. *Candida* pericarditis is found after cardiac surgery and in patients with impaired host defenses or severe debilitating underlying diseases. *Histoplasma* infection occurs in endemic areas, including the Ohio and Mississippi River valleys.

**Pathophysiology**

Purulent pericarditis occurs by several mechanisms: (1) spread from an adjacent infection, such as pneumonia or empyema; (2) hematogenous spread from a distant site; (3) direct inoculation of bacteria (trauma or procedure); and (4) spread from an intra-cardiac source. The most common mechanism is spread from a distant site.

**Clinical Features and Diagnostic Testing**

Purulent pericarditis usually manifests as a febrile illness lasting 2 or 3 days. Common presenting signs include tachycardia, dyspnea, hepatomegaly, elevated central venous pressure, chest pain, friction rub, and leukocytosis. The most common presentation is a hospitalized patient with a serious underlying disease who initially improves after treatment of the primary process but later develops fever, dyspnea, chest pain and a pericardial effusion. The search for a fever source is usually not successful, and the patient gets worse until a pericardial source is considered. Pericardiocentesis is necessary to establish the diagnosis, obtain fluid for microbiologic studies, and relieve cardiac tamponade.

**Management and Disposition**

Pericardiectomy is the traditional treatment of choice. Indwelling catheters, coupled with lavage, antibiotics, and fibrinolytics, may avoid the need for surgery. Patients require admission for intravenous antibiotics or antifungals and cardiorespiratory monitoring. Fibrinolytic therapy may reduce the rate of constrictive pericarditis when surgery is not an option.

The overall survival rate for purulent pericarditis is approximately 30% with antibiotic therapy alone and 50% when combined with early surgical drainage. In addition to complications related to sepsis and tamponade, long-term sequelae include constrictive pericarditis.

**PNEUMOPERICARDIUM**

**Principles**

Pneumopericardium and pyopneumopericardium are rare. Pneumopericardium may be caused by diseases that can lead to formation of fistulae between the pericardial and pleural space, bronchial tree, or upper gastrointestinal tract. It may result from bronchial carcinoma or infection with gas-producing microorganisms, or it can be idiopathic. Pyopneumopericardium may result from trauma, foreign body, ingestion of caustic substances, or invasive procedures.

Spontaneous pneumopericardium is caused by an increase in intra-alveolar pressure above atmospheric pressure, resulting in rupture of alveoli and is associated with myriad causes including asthma, labor, barotrauma from positive-pressure ventilation, or Valsalva maneuvers, including weightlifting, and even recreational drug inhalation from positive-pressure devices (huffing).

**Clinical Features and Diagnostic Testing**

Physical findings depend on the quantity of fluid and gas in the pericardial space. Heart sounds can be of variable intensity, change depending on body position, and have a metallic quality that may be accompanied by splashing sounds. *Hamman’s sign* and *medi-astinal crunch* are the terms used for a loud, crunching sound associated with pneumopericardium or pneumomediastinum and is diagnostic for the presence of mediastinal air. The diagnosis of pneumopericardium is confirmed by chest radiograph, CT scan, or ultrasound. Clinical sequelae of tension pneumopericardium are similar to acute cardiac tamponade.

**CONSTRICITVE PERICARDITIS**

**Principles and Pathophysiology**

Constrictive pericarditis may be a late consequence of acute pericarditis of virtually any cause. The incidence has increased as a result of improved survival in patients with chronic renal disease.

Constrictive pericarditis results from fibrous reaction of the pericardium. The key pathophysiologic feature is impaired diastolic filling from external cardiac compression caused by the thickened pericardium. In advanced cases, the visceral and parietal pericardial layers may be adherent.

Because the pericardium limits volume, ventricular filling is rapid and completed within the first third of diastole, after which left ventricular volume and pressure remain unchanged.

**Clinical Features**

The symptoms and signs of constrictive pericarditis are identical to those of CHF. Dyspnea, fatigue, and weight gain are the most common complaints. Hepatomegaly, marked pitting lower extremity edema, and ascites can be seen on physical examination. The characteristic auscultatory finding of constrictive pericarditis is a pericardial knock in early diastole. A friction rub may also be heard.

**Diagnostic Testing and Management**

The diagnosis is considered in a patient with right-sided heart failure symptoms. Heart size on the chest radiograph is typically normal. Pericardial calcification is suggestive when present. Liver function tests are consistent with passive congestion. ECG findings include low QRS voltage, nonspecific ST-T wave abnormalities, and atrial dysrhythmias.

Doppler echocardiography may help differentiate constrictive pericarditis from RCM or cardiac tamponade. There is a quick uptake in chamber filling and a shift in the ventricular septum that are diagnostic. Cardiac catheterization and simultaneous measurement of right ventricular and left ventricular end-diastolic pressures or endomyocardial biopsy may be necessary.
Pericardiectomy is the therapy of choice, although is associated with a mortality as high as 10%.27

MYOCARDIAL DISEASES

MYOCARDITIS

Principles

The term myocarditis was coined initially by Sobernheim in 1837. Romberg reported the association with scarlet fever and typhus in 1891, and “isolated idiopathic interstitial myocarditis” was described by Fiedler in 1899.

Pathophysiology

Some degree of myocarditis is detected in almost 10% of routine autopsies but is often not recognized clinically. The overall incidence is unknown and probably underestimated. The coxsackie B virus was originally named as the causative organism. The predominant agents in the 1990s were the adenoviruses, followed by parvovirus 19 and human herpesvirus 6 in the 2000s. Any infectious agent can cause myocarditis (Box 72.2). The etiology varies by patient age and region. Worldwide, Chagas’ disease is a leading cause, especially in South America.

Myocarditis occurs by (1) necrosis from direct invasion of an offending infectious agent and its replication within or near myocytes, (2) destruction of cardiac tissue from infiltration of host cellular immune components or from cytotoxic effects of host immunity activated by the infectious agent, or (3) the toxic effect of exogenous or endogenous chemicals produced by a systemic pathogen. Three stages of disease have been proposed: (1) acute (early after infection), with viral cytotoxicity and focal necrosis; (2) subacute, in which there is an increase in humoral factors leading to autoimmune injury; and (3) chronic, in which there is diffuse myocardial fibrosis and cardiac dysfunction that may lead to dilated cardiomyopathy (DCM). Traditionally, in children the pathologic changes are more often related to direct viral damage, whereas immunologic changes are more often related to direct viral damage in adults.

Our current understanding of the disease builds on this foundation.28-29 In the first stage, the type of virus matters. For example, enterovirus enters cells and a single strand RNA is reversely transcribed into positive strand for virus replication. This causes direct myocyte lysis followed by inflammatory changes. Other viruses infect the endothelial cells and cause inflammation. Host injury response, apoptosis and cell remodeling all contribute to the pathophysiology. This heterogeneity of virus and host response partially explains the variable clinical presentations.30

The activation T cells and B cells and antibody production begins the second phase. Inflammatory proteins are activated and cardiac autoantibodies develop. There is a higher concentration of anti–β-myosin antibodies in patients with myocarditis and DCM than in controls. Because myocarditis is linked to the development of DCM (up to 16% of cases in adult and 46% in children), idiopathic DCM after myocarditis may be predominantly autoimmune in origin, resulting from either shared antigens or molecular mimicry.31 The amino acid sequences of the coxsackie B virus and β-myosin heavy chain protein are similar. An immune response to the former yields damage to the latter (molecular mimicry).

Clinical Features

Flulike signs and symptoms, including fever, fatigue, myalgias, vomiting, and diarrhea, are usually the first manifestations of myocarditis. The most common presentation in children is dyspnea. In adults, it is dyspnea, chest pain, and dysrhythmias. Altered vital signs include fever, tachycardia, tachypnea, and, uncommonly, hypotension. Toxic appearance or tachycardia disproportionate to the temperature may be the only physical findings. No symptom or sign is sensitive or specific and cardiac examination is often unremarkable. When chest pain or CHF occurs at initial presentation, the prognosis is worse.

In children, prominent physical findings include grunting respirations and intercostal retractions. Approximately 10% to 15% have rhonchi. Infants often have a fulminant syndrome characterized by fever, cyanosis, respiratory distress, tachycardia, and cardiac failure. When children have ventricular dysrhythmias, myocarditis and idiopathic DCM are commonly seen on endomyocardial biopsy, despite findings of a structurally normal heart by noninvasive studies. Long-term prognosis in children correlates with the severity of their initial presentation.

Diagnostic Testing

Common ECG changes include sinus tachycardia, a widened QRS, and low voltages. There may be a prolonged corrected QT interval, atrioventricular (AV) block, or AMI pattern.

Cardiac troponin may be elevated, although when in the course of the disease is unknown. The prognostic significance of elevation is not known, although one can assume that a higher level correlates with more myocardial damage and a negative troponin does not rule out the diagnosis. The WBC count, C-reactive protein (CRP), and ESR may be elevated or normal and so are not of diagnostic value. The echocardiographic features of myocarditis, although nonspecific, include reduced left ventricular ejection fraction, global hypokinesis, and regional wall motion abnormalities. Contrast-enhanced MRI or nuclear studies may be diagnostic. Acute and convalescent viral titers are positive in less than 40% of cases.

**BOX 72.2**

Infectious Causes of Myocarditis

- Adenovirus
- Chagas’ disease
- Coxsackie B virus
- Chlamydia
- Cytomegalovirus
- H1N1 virus
- Hepatitis A
- Hepatitis B
- Hepatitis C
- Human herpesvirus 6
- Influenza A
- Influenza B
- Lymphocytic choriomeningitis virus
- Mononucleosis
- Mumps
- Mycoplasma
- Parainfluenza
- Parvovirus 19
- Rabies
- Rubeola
- Rubella
- Streptococcus
- Toxoplasma gondii
- Varicella zoster
- Legionella
PART III  Medicine and Surgery  |  SECTION THREE  Cardiac System

Endocardial biopsy, the historical gold standard, has variable sensitivity and specificity owing to sampling error (Fig. 72.4). Histologic criteria for myocarditis are present in only 5% to 30% of patients with clinically suspected myocarditis and up to half of patients with DCM. Molecular genetic probes, such as polymerase chain reaction assays, are used to supplement standard histologic analysis. In addition, polymerase chain reaction analysis of tracheal aspirates of intubated patients with myocarditis shows a correlation with endocardial biopsy. Because of the limitations of biopsy, magnetic imaging may become the diagnostic test of choice and the next gold standard.31

**Differential Diagnosis**

Myocarditis can masquerade as AMI with severe chest pain, ECG changes, elevated cardiac markers, and heart failure. Patients with myocarditis are usually young and have few risk factors for coronary artery disease. ECG abnormalities may extend beyond the distribution of a single coronary artery. There may be global, rather than segmental, wall motion abnormalities on echocardiography. In myocarditis, chest pain continues, but there are no further ischemic ECG changes. The diagnosis of myocarditis should also be considered in an otherwise healthy patient with symptoms and signs of new CHF or dysrhythmias. Coronary angiography is usually normal in myocarditis, which should prompt consideration of endomyocardial biopsy.

**Management**

Treatment is supportive and aimed at preserving left ventricular function. This may extend from simple limitation of activity to rhythm and CHF treatment, extracorporeal membrane oxygenation, ventricular assist devices, and eventual cardiac transplantation.

Therapy is stage specific. In the first phase, demonstration of replicating virus suggests that early antiviral agents, such as beta-interferon or ribavirin, may be effective. Unfortunately, the diagnosis is often made after the initial viral phase. Agents active at the coxsackievirus/adenovirus receptor present an intriguing theoretic approach.

Multicenter trials of immunosuppressive therapy for the subacute phases have shown no benefit. Efforts to identify patient and treatment subsets in which immunosuppressive therapy may be beneficial are ongoing. Many researchers believe that there is a place for immunotherapy despite the evidence to date. High-dose immunoglobulin therapy may be associated with improved recovery of left ventricular function and better survival during the first year after presentation in a pediatric population.

In the chronic stage, CHF symptoms predominate and standard pharmacologic treatment for CHF is indicated. In some cases, the deterioration of cardiac function is reversible with the aid of a ventricular assist device. These devices have been used successfully over extended periods, including up to 70 days. Their use should be considered before transplantation, because some patients recover enough function to avoid transplantation.

**Disposition**

All patients should be admitted to the hospital to a monitored bed, and those with persistent hemodynamic instability require intensive care. Complications of myocarditis include ventricular dysrhythmias, left ventricular aneurysm, CHF, and DCM.

The mortality rate is 20% at 1 year and 50% at 5 years, despite optimal medical management and has not changed in over 25 years. Ejection fraction and right ventricular function 1 year after initial presentation may be the best predictors of subsequent survival. The long-term prognosis in survivors is variable.

Patients who undergo transplantation because of myocarditis have decreased 1-year survival compared with patients who undergo transplantation for other reasons including a higher allograft rejection rates. The overall 5-year survival rate for children is 70%.

**CHAGAS’ DISEASE**

**Principles and Clinical Features**

Chagas’ disease is one of the leading causes of myocardial disease in many countries, particularly Central and South America. Chagas’ disease is caused by the protozoan _Trypanosoma cruzi_ with transmission by insect vectors.

Most seropositive patients never develop symptoms. Acute infection presents as a nonspecific viral-like illness, then latent phase, then cardiac phase with conduction abnormalities, and then DCM. Systemic symptoms include fever, hepatic or splenic enlargement, and unilateral periorbital edema. Cardiac manifestations include angina-like chest pain, dysrhythmias, embolic episodes, heart failure, conduction abnormalities, multifocal ventricular premature contractions, and abnormal ST segment and T wave abnormalities. Ventricular tachycardia is common and considered by some to be a hallmark of disease. Syncopal or near-syncopal episodes occur in nearly two-thirds of patients.

**Diagnostic Testing**

Serum testing for parasites establish the diagnosis, as does measuring anti-IgG for _T. cruzi_. Chagas’ disease should be considered in patients with new cardiac symptoms and a Latin American travel or immigration history. Echocardiography may show a left ventricular apical aneurysm or scar, which is a reliable marker of the disease.

**Management**

Chagas’ disease is treated with variable success by the antitrypanosomal drugs benznidazole and nifurtimox. These are available from the Centers for Disease Control and Prevention (CDC). Amiodarone may be useful to treat ventricular tachycardia. An angiotensin-converting enzyme (ACE) inhibitor may be useful for CHF. Up to 30% of patients develop CHF from 5 to 30 years after initial infection. Increased world attention, with elimination of the vector and improved blood donation screening, especially for platelet transfusions, is decreasing the incidence of this disease.
TRICHINOSIS

Trichinosis is caused by ingestion of the cysts of *Trichinella spiralis* in undercooked meat. Historically, pork was the most commonly implicated meat, but *Trichinella* has been eradicated for many decades from commercial domestic pork in the United States. It is most likely caused by wild game in the United States. The acute illness consists of fever, myalgias, muscle tenderness, neck stiffness, and a characteristic peri orbital edema. Laboratory studies reveal an eosinophilia and often elevated creatine phosphokinase.

Myocardial involvement is present in approximately 20% of clinically diagnosed cases and appears in the second or third week of illness, when other symptoms are declining. Cardiac manifestations include chest pain, dyspnea, cardiomegaly, dysrhythmias, and CHF. ECG findings, such as nonspecific ST-T wave abnormalities and conduction blocks, may appear transiently, even in the absence of cardiac symptoms.

The diagnosis is usually established with serologic studies or biopsy of any symptomatic muscle group. Treatment usually involves corticosteroids together with anthelminthic drugs, such as albendazole and mebendazole.

DIPHTHERIA

Myocardial involvement is clinically evident in 10% to 25% of cases and is the major cause of death. Early signs of myocarditis are tachycardia and faint heart sounds. Cardiac enzymes are often elevated. Prolongation of the PR interval and ST-T wave abnormalities occur early in the course of the disease. Bundle branch block or complete heart block, when they occur, precede total circulatory collapse and are associated with a poor prognosis. Treatment with oral carnitine is associated with a lower incidence of mortality, heart failure, and severe conduction blocks. Diphtheria is rare in the United States.

LYME DISEASE

Epidemiology and Clinical Features

Lyme disease is caused by infection with the spirochete *Borrelia burgdorferi*. Lyme disease–related carditis occurs weeks to months after the onset of erythema migrans. Cardiac complications occur in 4% to 10% of patients, most commonly a conduction delay, caused by a reversible effect on the AV node. Pericarditis and CHF also occur.

Lyme disease–related carditis should be suspected in otherwise healthy persons with unexplained heart block and potential exposure to ticks in an endemic area. Lyme disease is diagnosed by identification of the spirochete with serologic testing. A screening ECG should be performed whenever the diagnosis of Lyme disease is suspected.

Temporary pacemaker placement is often required in unstable patients. Antibiotic therapy with intravenous penicillin or oral doxycycline is effective and can reverse AV block. Erythromycin should be prescribed in place of tetracycline in young children. Ceftriaxone is also effective. Most patients recover completely, and a permanent pacemaker is rarely needed.

OTHER CAUSES OF MYOCARDITIS

The cardiac manifestations of acquired immunodeficiency syndrome (AIDS) are diverse and cause death in at least 6% of patients with HIV. The prevalence of left ventricular dysfunction in adult AIDS patients is approximately 20%. Myocarditis is described in approximately 46% of AIDS patients undergoing postmortem examination. HIV treatment may also lead to cardiac toxicity. Pentamidine can cause torsades de pointes ventricular tachycardia. Zidovudine and dideoxyinosine also can lead to cardiac dysfunction.

Cardiac involvement with *Legionella pneumophila* is uncommon, although the heart may be the only affected organ. Clinical symptoms resemble pericarditis and myocarditis, including dysrhythmias and conduction blocks. After treatment with erythromycin, normal cardiac function may return.

Cardiac *Toxoplasma* infection may lead to clinically significant disease. Infection is well described in recipients of bone marrow and cardiac transplantation. Immunocompromised patients with toxoplasmic myocarditis may have bundle branch block, CHF, pericarditis, and dysrhythmias as a result of lesions in the conducting system. Untreated toxoplasmic myocarditis is fatal.

Myocarditis associated with *M. pneumoniae* may be caused by direct invasion of the myocardium, an autoimmune mechanism, or intravascular coagulation. Miliary tuberculosis, including tuberculosis myocarditis, can produce granulomas within the myocardial conduction system that can precipitate fatal dysrhythmias. Sudden death can occur secondary to *Chlamydia pneumoniae* myocarditis. Myocarditis, presumably mediated by exotoxin, is associated with *Shigella* infection. Cardiac involvement of the conduction system and the pericardium also may occur in dermatomyositis and polymyositis. Patients are usually asymptomatic, but pericarditis, myocarditis, and dysrhythmias can occur.

Myocarditis can also occur with chemotherapeutics, most notably doxorubicin, which can cause both acute and chronic cardiotoxicity. Manifestations of acute cardiotoxicity include dysrhythmias, pericarditis, myocarditis, and left ventricular dysfunction.

COCAINE CARDIOTOXICITY

Cocaine causes ischemia, myocarditis, and DCM. Myocarditis is a common autopsy finding in patients with cocaine abuse. The mechanism is largely unknown. Theories include increased sympathomimetic effect, severe oxidative stress, and metabolite interaction with ion channels. Cocaine has a direct, negative inotropic effect on cardiac muscle. It is the cause of many deaths. Patients who die with detectable cocaine levels have myocarditis and myocardial contraction bands more often than controls. The severity correlates with the serum and urine concentrations of cocaine. This may supply the anatomic substrate for ventricular dysrhythmias.

CARDIOMYOPATHIES AND SPECIFIC HEART MUSCLE DISEASE

Principles

Cardiomyopathies are a heterogeneous group of diseases associated with mechanical or electrical dysfunction. They usually exhibit inappropriate ventricular hypertrophy or dilation and have a variety of causes. Many of these diseases result from genetic mutations.

Pathophysiology

A variety of pathologic processes may initiate myocyte injury. When injury occurs, common pathophysiologic pathways are activated. These pathways involve neurohumoral factors, immune factors, and cytokines that cause myocyte dysfunction with subsequent remodeling, either hypertrophy or dilation. There is an increase in interstitial fibrosis that impairs ventricular filling and leads to increased metabolic demand. At a cellular level, the pathophysiologic derangement may be the troponin complex, intracellular concentration of calcium, myocardial subproteins, or the sarcomere. These lead to alteration in the myocytes ability to
contract, which causes clinical pathology. The cardiac microvascular circulation also changes and is an independent predictor of morbidity and mortality. Although traditionally defined by organ level pathology, the classification of cardiomyopathies may evolve into a unified theory that shows all types of cardiomyopathy to be variations of a common genetic, anatomic, and humoral pathophysiologic processes. The exact correlation between genotype, phenotype, and clinical presentation is unknown, as is the point when changes at the molecular level transition from compensatory to pathologic.

**DILATED CARDIOMYOPATHY**

**Principles**

DCM is a spectrum of disorders that have in common a dilated and failing heart. The incidence of DCM is estimated to be 5 to 8 cases per 100,000 adults and 0.57 cases per 100,000 children. Many cases previously thought to be of unknown cause may be genetic or secondary to infection. Myocarditis is the most common cause of DCM in children. The true incidence is probably underestimated because many asymptomatic cases remain undiagnosed. Thirty percent to 40% of cases have a genetic cause. More than 35 gene mutations have been discovered, primarily coding for cytoskeleton or sarcomere proteins.

DCM affects men more than women, African Americans more than whites, and may occur in any age group, with 40 to 65 years old being the most common. Risk factors include ethanol and tobacco abuse, pregnancy, hypertension, and infection.

**Pathophysiology**

There are both primary and secondary causes. Possible pathophysiologic causes include myocardial inflammation mediated by cytokines, macrophages, and natural killer cells; local inflammation caused by the release of cytokines by infiltrating lymphocytes; direct reaction of antibodies with receptors on myocardial muscle; toxins, such as ethanol, impairing myocardial biochemical processes; and loss or dysfunction of myocardial matrix proteins. The result is impaired myocardial force generation, which initiates a vicious cycle that increases the burden on the remaining cells that leads to increased stress, more work, and more cell death. There may also be a genetic predisposition to the pathology involved.

**Clinical Features**

Symptoms have an insidious onset. Left-sided heart failure occurs as the initial manifestation in 75% of adults, with dyspnea (usually with exertion or while supine) being the major symptom. Exacerbation of coronary artery or renal disease, dietary indiscretion, and medication noncompliance are key contributors. CHF symptoms are the most common presentation in children. Chest pain on exertion is the initial symptom in 10% of adults, and systemic or pulmonary emboli are the initial manifestation in 4%. Right-sided heart failure is a late and ominous sign.

**Diagnostic Testing**

ECG findings are nonspecific and may include poor R wave progression, intraventricular conduction delay, or a left bundle branch block. Holter monitoring may show frequent premature ventricular contractions and occasional ventricular tachycardia. Sudden death is uncommon. The chest radiograph reveals cardiomegaly.

Echocardiography shows left ventricular dilation, reduced systolic function, and variable wall motion abnormalities. Abnormal ventricular contractility defines DCM, and an ejection fraction less than 45% is required for diagnosis. End-diastolic and systolic volumes are increased, as are pulmonary capillary wedge pressure and central venous pressure.

Endomyocardial biopsy may also be necessary, although histologic abnormalities are nonspecific. New histochemical, immunologic, and molecular biologic techniques improve the diagnostic yield, especially for infectious causes. MRI may help. Right-side failure should have occult atrial septal defect ruled out. Because many patients may have a genetic defect, obtain a family history and consider genetic counseling.

**Management and Disposition**

Therapy includes supportive measures, such as adequate rest, weight control, abstinence from tobacco, moderate salt and ethanol consumption, and structured physical activity. Medical treatment includes standard measures for CHF.

ACE inhibitors reduce morbidity and mortality. Isosorbide dinitrate and hydralazine, spironolactone, and the angiotensin receptor-blocking agents also prolong survival. Beta-blockers can reduce symptoms and improve left ventricular function, functional capacity, and survival. In addition, the improvement in cardiac function associated with beta-blockers is associated with changes in expression of genes encoding for alpha- and beta-myosin heavy chain and sarcoplasmic reticulum calcium adenosine triphosphate.

Implantable defibrillators improve survival and should be considered in patients with an ejection fraction less than 30% or symptoms for more than 9 months. Antidysrhythmics are not usually effective. There is encouraging research indicating that stem cell transplant may improve survival.

**Outcome**

Patients with DCM show progressive deterioration. Because medical therapy usually fails, DCM is the leading indication for cardiac transplantation. Mortality is 18% by 1 year, 35% by 5 years, and 50% by 10 years. The clinical course for children is variable, with a better prognosis in young children. Some children show delayed, spontaneous, and unexplained improvement.

**HYPERTROPHIC CARDIOMYOPATHY**

**Principles**

Hypertrophic cardiomyopathy (HCM) is a complex disorder with variable clinical manifestations. The prevalence is estimated to be 1 in 500 persons in the general population. It affects all races, men and women equally, and can manifest at any age. It is the most commonly inherited cardiac disease.

**Pathophysiology**

HCM is a disease involving abnormalities of heart muscle at the anatomic, cellular, and genetic levels. Specifically, it is a genetic disease of sarcomere proteins. The defining anatomic feature of HCM is a hypertrophied left ventricle in the absence of another cause. The dimensions of both ventricles are small or normal. Atrial dilation is common. Ventricle thickening is usually asymmetrical and varied. It involves the septum more than the free wall. The extent of hypertrophy correlates with the manifestation of the disease. Histologically, individual muscle cells are hypertrophied, with a disorganized, characteristic whorled pattern and fibrous scar tissue. Sarcomere disarray is the histologic hallmark.

HCM is an autosomal dominant disease caused by mutations in genes that encode for sarcomere contractile proteins.
Twenty-three genes and more than 470 different mutations have been identified. More than 18 of these genes code for sarcomere proteins, including a missense mutation for β-myosin heavy chain (which constitutes 30% of myocardial protein), as well as myosin-binding protein C and troponin T. Because many genes are involved, there are many clinical expressions of the disease.39,44

The hypertrophy in HCM may be a compensatory response to the cardiac protein abnormalities. In vitro studies show that mutant β-myosin heavy chain protein exhibits impaired contractility and disrupts the normal sarcomere. The usual cardiac response to physiologic stress is hypertrophy, dilation, or both. Gene mutations lead to abnormal proteins, changed cellular structure and impaired function owing to fibrous changes in the sarcomere. This compensatory tissue hypertrophy manifests as HCM.

Patients with HCM have an abnormal echocardiogram or cardiac MRI that shows asymmetric left ventricular hypertrophy and hyperdynamic ventricles. There may be outflow obstruction, which usually occurs with exertion. The thickness of the ventricles and degree of outflow obstruction reflect the amount of fibrous changes and correlate with disease severity.11 The pathophysiology involves impaired ventricular filling during diastole.

Genetic studies of families with HCM identify specific mutations that correlate with sudden cardiac death. In families with Arg403Gln mutation, less than half of affected family members survive past 45 years old. Genetics alone does not account for the clinical manifestation of HCM, because patients with the same genotype differ in phenotypic expression and clinical course.

Clinical Features

Although HCM occurs at all ages, the average age at diagnosis is between the ages of 30 and 40 years old. Approximately 2% of cases are diagnosed in children younger than 5 years old, 7% are diagnosed before 10 years old, and presentations vary widely. It may be found in relatives of patients who have HCM.

Often, the first presentation of disease is sudden death, which most commonly occurs during periods of exertion, and HCM gained notoriety after the press coverage of the sudden deaths of several young athletes. For patients who do not initially experience sudden death, 90% will have a presenting complaint of shortness of breath. Other symptoms include chest pain, syncope, near-syncope, and palpitations. Large-scale ECG screening of young athletes occurs in Italy, although it is controversial and most likely would not be cost-effective in the United States.45-47

Physical examination may reveal a loud S4 gallop and a harsh crescendo-decrescendo midsystolic murmur. This murmur is accentuated by the Valsalva maneuver or changing from a standing to a squatting position. Other physical findings may include a bifid arterial pulse, paradoxical splitting of the second heart sound, and, rarely, a mitral leaflet septal contact sound, which are all difficult to hear in a busy ED. Many dysrhythmias are seen in HCM, including premature atrial and ventricular contractions, multifocal ventricular ectopy, and ventricular tachydysrhythmias with atrial fibrillation being the most common. In the ED, the diagnosis should be considered in anyone with a family history, characteristic murmur, and cardiopulmonary symptoms not explained by other life-threatening conditions.

Diagnostic Testing

Patients with suspected HCM should have an ECG, chest radiograph, and echocardiogram. The ECG is abnormal in approximately 90% of patients. The most common abnormalities are left ventricular hypertrophy, ST segment alterations, T wave inversion, left atrial enlargement, abnormal Q waves, and diminished or absent R waves in the lateral leads. The chest radiograph may be normal or may show left ventricular or atrial enlargement.

Echocardiography is the most important clinical diagnostic strategy. Findings include asymmetrical left ventricular hypertrophy, left ventricular outflow tract narrowing, a small left ventricular cavity, and reduced septal motion. The dynamic characteristic of HCM distinguishes it from the discrete forms of obstruction to ventricular flow. Doppler techniques help assess the severity of this obstruction at rest and with provocative maneuvers. Left ventricle obstruction at rest is an independent predictor of heart failure. Magnetic resonance is helpful when the echocardiogram is not, including assessing risk for sudden death.46-49 Electrophysiologic studies may show dysrhythmias but are not more predictive of sudden death than clinical factors. Cardiac catheterization may be necessary to confirm the diagnosis. Genetic screening may be helpful to predict other family members at risk.

Differential Diagnosis

HCM mimics many disorders. In individuals with murmurs, HCM may be confused with valvular diseases or a ventricular septal defect. In the absence of a murmur, symptoms may suggest mitral valve prolapse, primary pulmonary hypertension, or coronary artery disease. ECG changes, without a history of preceding MI, may also suggest HCM.

Management

Beta-blocker therapy is the mainstay of therapy. They modulate the effect of catecholamines on the outflow gradient which prolongs diastole, increases ventricular filling, and results in symptomatic improvement and exercise tolerance. Calcium channel blockers are also useful. Verapamil reduces obstruction, decreases contractility, and improves diastolic relaxation and filling. Verapamil is contraindicated when conduction blocks are present. Disopyramide may be added if beta-blockers fail.

Nitroglycerin, the traditional initial ED management for chest pain, should be avoided in HCM-associated chest pain because it decreases ventricular volume. Amiodarone is the drug of choice for treatment of ventricular dysrhythmias and atrial fibrillation. Phenytoin and intravenous fluids are the choices for hypotension. Implantable cardioverter defibrillators are indicated for patients with sudden death or a risk factor for it.

Surgical treatment is reserved for patients with large (>50 mm Hg) systolic gradients, severe symptoms, and poor quality of life who do not respond to medical therapy. The most common procedure is septal myomectomy. Dual-chamber pacing decreases outflow gradient and improves symptoms, but it does not improve outcome.

Disposition

The natural history of HCM is variable and probably reflects the many different genetic causes. The annual mortality rate is 0.7%. The clinical course is either heart failure, atrial fibrillation, or sudden death.50

The onset of atrial fibrillation in patients with HCM may precipitate marked hemodynamic compromise and severe CHF. Cardioversion and rate control should be attempted. The risk of stroke is high and anticoagulation is indicated.

Risk factors for sudden death include malignant genotype, unexplained syncope, sudden death in first-degree relatives, abnormal blood pressure response to exercise, greater than 30-mm ventricular thickening and non-sustained ventricular tachycardia.43 These factors all reflect the extent of interstitial fibrosis.

Patients with HCM initially diagnosed in the ED should have strenuous physical activity specifically proscribed until the patient...
has been evaluated by a cardiologist. Patients with HCM who have angina, syncope, near-syncope, dysrhythmias, and abrupt hemodynamic changes should be hospitalized.

**RESTRICTIVE CARDIOMYOPATHY**

**Principles**

RCM is a gradual and progressive limitation of ventricular filling secondary to myocardial infiltration. RCM is the least common type of cardiomyopathy, accounting for less than 5% of all cases. The most common cause in the United States is amyloidosis. Other causes include sarcoidosis, hemochromatosis, scleroderma, neoplastic cardiac infiltration, glycogen storage disorders, Fabry’s disease, Gaucher’s disease, and mutations related to myocardial muscle proteins.

**Pathophysiology**

Restriction of ventricular filling results in low ventricular volumes, high end-diastolic ventricular pressures, and decreased cardiac output. Systolic function is maintained. Grossly, there is atrial enlargement and small ventricles. As the disease progresses the ventricular cavities may become obliterated by fibrous tissue, scarring, or thrombus.

**Clinical Features and Diagnostic Testing**

Symptoms are those of worsening diastolic dysfunction and include exercise intolerance (cardiac output cannot be increased because ventricular filling is compromised), elevated central venous pressure, peripheral edema, pulmonary edema, and S3 and S4 gallops. Children demonstrate failure to thrive.

Differentiation from constrictive pericarditis requires CT, MRI, or Doppler echocardiography. Pericardial calcification favors a diagnosis of constrictive pericarditis over the diagnosis of RCM. Myocardial biopsy may be necessary.

**Management and Disposition**

Most of the underlying causes of RCM are untreatable. The exception is hemochromatosis. Symptomatic treatment with vasodilators and diuretics may help. Patients with RCM should be maintained in sinus rhythm, because loss of the atrial contribution to cardiac output results in hypotension. Transplantation is a possibility in some patients with better survival than controls. RCM is relentless, with 90% of patients dying within 10 years of diagnosis.

**ARRHYTHMOGENIC RIGHT VENTRICULAR CARDIOMYOPATHY**

Arrhythmogenic right ventricular cardiomyopathy (ARVC) is a genetic disease with ventricle scarring. Myocytes are replaced by fibrous or fatty tissue. Up to 75% of the time the left ventricle is also involved. ARVC is autosomal dominant with incomplete penetrance and variable expression. The genes responsible for ARVC code for the proteins of the intercalated discs of cardiac myocytes. ARVC is clinically characterized by dysrhythmias, palpitations, syncope, sudden death, and heart failure. ECG shows wide QRS, left bundle branch pattern, and inverted T waves. MRI may show scarring and direct confirmatory biopsy. Treatment is exercise avoidance. Dysrhythmias should be treated with amiodarone and sotalol. An implantable cardioverter-defibrillator (ICD) should be used. Evidence shows that outcomes are not improved by cardiac ablation. Patients and relatives should be sent for genetic counselling.

**PERIPARTUM CARDIOMYOPATHY**

**Principles**

Peripartum cardiomyopathy (PPCM) is uncommon and represents less than 1% of the cardiovascular problems associated with pregnancy. PPCM is defined as an idiopathic cardiomyopathy presenting with heart failure secondary to left ventricle systolic dysfunction towards the end of pregnancy or in the months following delivery, where no other cause of heart failure is found.

The cause of PPCM is unknown. Risk factors include myocarditis, excessive use of tocolytics, preeclampsia, advanced maternal age, multiparity, twins, obesity, cocaine use, and genetic predisposition. The incidence is estimated to be 1 case of PPCM per 13,000 to 15,000 live births.

**Clinical Features and Diagnostic Testing**

PPCM is clinically identical to DCM. Patients usually have symptoms of CHF but may also have chest pain, palpitations, or thromboembolism. Physical examination often reveals tachycardia, tachypnea, pulmonary rales, an enlarged heart, and an S3 heart sound.

The ECG may show left ventricular hypertrophy or nonspecific ST-T wave changes. On echocardiography, all four chambers are enlarged with reduction in left ventricular systolic function.

**Management and Disposition**

Treatment of PPCM includes limitation of physical activity, beta-blockers, alteration of preload with nitrates and diuretics, increase in ventricular contractility, and afterload reduction. ACE inhibitors and angiotensin receptor blockers should be avoided, if possible, in pregnancy and during breast-feeding. Hydralazine and labetalol are effective choices.

Subsequent pregnancies have a 33% to 50% recurrence and high mortality rate. Mortality for PPCM in the United States is approximately 2%. Half of the survivors have complete or near-complete recovery of cardiac function within the first 6 months. Patients who do not recover completely show either continuous clinical deterioration or persistent left ventricular dysfunction. Factors associated with favorable prognosis include small left ventricle diastolic dimension (<5.5 to 6.0 cm), elevated systolic function (ejection fraction >30% to 35% and fractional shortening >20%) at the time of diagnosis, absence of troponin elevation and absence of left ventricular thrombus. In the ED, patients with signs of hemodynamic instability or failure to maintain oxygenation should be admitted for treatment and fetal monitoring.

**TAKOTSUBO CARDIOMYOPATHY**

**Principles**

Takotsubo cardiomyopathy (TCM), also known as stress cardiomyopathy, broken heart syndrome, or tako-tsubo cardiomyopathy, was first reported from Japan in 1991 (Box 72.3). In Japanese, tako-tsubo means octopus trap. The term was used because the cardiac abnormality observed in this disease resembles that of the device used to catch octopi.84 There have been hundreds of cases reported in the medical literature since that time. The pathophysiology of TCM is a sudden temporary myocardial weakening. The exact mechanism is unknown. Speculated causes include stress hormones, microvascular spasm, focal myocarditis, and cellular level muscle changes. It may not be correct to think of TCM as a cardiomyopathy, because the triggers lie elsewhere and the cardiac effect is the outcome.
CHAPTER 72  Pericardial and Myocardial Disease

Sudden Death

Approximately 25% of sudden deaths in patients younger than 21 years old can be attributed to disease of the myocardium. Cardiac causes include myocarditis, HCM, and anomalous coronary artery circulation. Prodromal symptoms are reported in more than half of the patients with cardiac causes, most commonly chest pain (25%) in patients older than 20 years old and dizziness (16%) in patients younger than 20 years old. The distribution of sudden death causes by age is as follows:

- Younger than 20 years old: Myocarditis 22% and HCM 22%
- 20 to 29 years old: Myocarditis 22% and HCM 13%
- 30 to 39 years old: Myocarditis 11% and HCM 2%

Coronary artery disease becomes the leading cardiac cause (58%) of sudden death in people older than 30 years old. HCM and anomalous coronary arteries are seen more often in sports-related deaths.

Clinical Features and Diagnostic Testing

TCM presents in menopausal females after an emotional stress. Symptoms include chest pain and dyspnea on exertion. Almost 90% of cases involve women. ECG is often consistent with an anterior MI. There are transient Q waves and ST elevation. Later, the ECG shows T wave inversion and a prolonged QT interval. Cardiac enzymes are elevated slightly and resolve to normal quickly. Coronary artery angiography shows no—or very little—disease. It is assumed that coronary artery spasm plays a role on some level. The diagnosis is made by left ventricular angiography or echocardiography that shows a ballooning of the apex during the acute phase of the disease. The involved area does not match a coronary artery anatomic distribution. MRI can also help establish a diagnosis.

Management and Disposition

In the ED, TCM is not distinguishable from AMI. Patients should be treated the same as any patient with acute coronary syndrome. Long-term treatment includes beta-blockers and ACE inhibitors. Most patients show complete resolution of symptoms and reversal to normal of their left ventricular apex ballooning and contractile function.

ION CHANNELOPATHIES

Principles

Several uncommon dysrhythmic diseases are caused by mutations of genes for ionic channel proteins, which are cell membrane transport proteins for sodium and potassium. These include long QT syndrome, short QT syndrome, and Brugada syndrome. In patients with normal heart anatomy and sudden death, 10% may be caused by a channelopathy, many of which are genetic based. Treatment is medication for rhythm control and referral for an ICD and genetic testing.

KEY CONCEPTS

- Pericarditis and myocarditis should be differentiated from acute myocardial infarction (AMI). Acute treatment is with nonsteroidal antiinflammatory drugs (NSAIDs) supplemented with colchicine.
- Cardiac tamponade is suspected in patients with dyspnea, distended neck veins, hypotension, and muffled heart sounds. Diagnosis is by ultrasound. Pericardiocentesis is both diagnostic and therapeutic.
- Myocarditis should be considered in any patient with the combination of viral illness symptoms and a new presentation of cardiac disease.
- Patients with newly diagnosed hypertrophic cardiomyopathy (HCM) should avoid strenuous exertion until evaluated by a cardiologist. Beta-blockers are the mainstay of therapy for HCM; nitrates should be avoided.
- Many of the cardiomyopathies have genetic origins. Send patients for cardiology evaluation and genetic testing.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
REFERENCES

PART III Medicine and Surgery | SECTION THREE Cardiac System

A. Further decision making after initial troponin evaluation
B. Nitroglycerin, aspirin 325 mg per os (by mouth) (PO), cardiology consultation
C. Nonsteroidal antiinflammatory drugs (NSAIDs) and reassurance
D. Reassurance and ibuprofen 800 mg tid for 7 days
E. Thrombolysis

Answer: A. The ECG shows findings consistent with acute pericarditis. Clinically, diffuse ST elevation is seen in leads I, II, II, aVL, aVF, and V2 to V6. In contrast to finding an acute myocardial infarction (AMI), ST elevations are concave upward in acute pericarditis rather than convex upward as seen with a myocardial infarction (MI). PR depression is also a frequent finding. As the acute pericarditis resolves, ST changes revert to normal, followed by T wave flattening and later deep symmetrical inversion, which may persist. NSAIDs are the mainstay therapy for uncomplicated pericarditis.

B. It indicates a greater degree of myocardial damage than those without pericarditis.
C. Large pericardial effusions are common.
D. The incidence of congestive heart failure (CHF) is unchanged.
E. The incidence of dysrhythmias is unchanged.

Answer: B. Both dysrhythmias and CHF are more common in patients who experience post-MI pericarditis. Large effusions are uncommon, and classic pericarditis ECG findings are often overshadowed by the changes of the recent or evolving MI.

72.3. Which of the following disorders is least likely to be associated with pericarditis?
A. Giant cell arteritis
B. Rheumatoid arthritis
C. Sjögren’s syndrome
D. Systemic lupus erythematosus (SLE)
E. Takayasu’s arteritis

Answer: E. Fifty percent of SLE patients have pericarditis discovered at autopsy. Approximately one-third of patients with rheumatoid arthritis and Sjögren’s syndrome develop evidence of pericarditis, with the former typically also having rheumatoid
nodules and valvular disease. Giant cell arteritis typically demonstrates a granulomatous myocarditis. Takayasu’s arteritis is a large cell vasculitis, typically affecting the aorta and/or its major branches. Pericarditis is very uncommon.

72.4. A 35-year-old woman presents with progressive dyspnea, chest pain, and cough over 5 days. She has a past history of Hodgkin’s lymphoma and is 2 years status postchemotherapy and mediastinal irradiation for malignant adenopathy. She is currently on no medications and does not smoke. Vital signs are: temperature, 100.2° F (37.9° C) oral; heart rate, 120 beats per minute; respiratory rate, 26 breaths per minute; blood pressure, 100/60 mm Hg; and oxygen saturation, 96% on room air. Physical examination is remarkable for 3-cm jugular venous distention at 45 degrees, clear lung fields on auscultation, tachycardia without a friction rub, trace pretibial edema, and weak peripheral pulses that disappear during expiration. Chest radiograph shows an enlarged cardiac silhouette and clear lung fields. What would be the most appropriate initial intervention?

A. Endotracheal intubation with rapid sequence induction
B. Enoxaparin 1 mg/kg intravenously
C. Helical computed tomography (CT) scan of the chest
D. Isotonic fluid bolus and emergent cardiac ultrasonography
E. Methylprednisolone 125 mg intravenously

Answer: D. This patient is presenting with pericardial tamponade, presumably malignant because of her history of lymphoma. Radiation pericarditis is also possible, and effusion would be possible in this circumstance. Pulmonary embolus is a consideration but less likely, given the picture of normal oxygen saturation and an enlarged heart. The initial intervention should be fluid loading to maintain venous return and cardiac output, followed by ultrasound confirmation and likely pericardiocentesis. Tracheal intubation is not currently indicated because improvement would be expected after effusion aspiration.

72.5. A 44-year-old man complains of swollen legs. He just finished two courses of prednisone for wheezing related to asthma. The first course was prescribed 6 weeks ago in the emergency department (ED), where he was diagnosed with new onset asthma and normal chest radiograph. The second course was prescribed by his family physician 2 weeks ago. The patient denies fever and chest pain and is still mildly short of breath, which is worse at night or with exertion. Examination shows bibasilar rales in his lungs, normal heart sounds, and +1 edema in both legs up to his knees. What is his diagnosis?

A. Asthma exacerbation
B. Idiopathic dilated cardiomyopathy (DCM)
C. Prednisone-induced edema
D. Prednisone-induced liver failure
E. Renal failure

Answer: B. The patient is unlikely to have a new diagnosis of asthma. He most likely had a viral process leading to reactive airway disease initially and a viral myocarditis later. Unfortunately now has a DCM and symptoms of congestive heart failure (CHF). Treatment is supportive.

72.6. A 16-year-old male presents in cardiac arrest suffered during a high school football game. He is successfully resuscitated in the emergency department (ED) and admitted to the intensive care unit (ICU). What is the most likely cause of his arrest and what should you tell the family?

A. Cocaine-induced dysrhythmia: Stop using drugs
B. Familial dysrhythmia: Seek cardiology evaluation
C. Hypertrophic cardiomyopathy (HCM): Seek genetic testing
D. Steroid-induced cardiac damage: Stop steroids and consult cardiology
E. Traumatic arrest: Wear more padding

Answer: C. HCM is a common cause of cardiac arrest in patients thought to be too young for coronary artery disease. It is a genetic disease with many different clinical expressions. Both the patient and all family members should be screened for HCM. Although screening may not predict future risk of sudden death, treatment and prevention could be considered.
CHAPTER 73

Infective Endocarditis, Rheumatic Fever, and Valvular Heart Disease

Joshua M. Kosowsky | Sukhjit S. Takhar

INFECTIVE ENDOCARDITIS

PRINCIPLES

Background and Importance

The natural history of infective endocarditis (IE) has undergone considerable changes in the antibiotic era. The older classifications of acute, subacute, and chronic have become less meaningful, immunologic phenomena, such as Osler’s nodes and glomerulonephritis, are rarely seen, and nosocomial infections from indwelling catheters and devices are increasing. Early diagnosis and treatment play a significant role in the clinical outcome because IE remains a disease that causes considerable morbidity and mortality.

Estimates of the incidence of IE in the United States vary widely, in part because of changing case definitions throughout the years but also because of differences in predisposing conditions among studied populations. Currently, the annual incidence of endocarditis in industrialized countries range between 3 to 10 cases/100,000.1,2 IE is increasingly a disease of older adults, with more than 35% of cases occurring in individuals older than 70 years.3 This reflects the pervasiveness of degenerative valve disease in older adults and the increased prevalence of prosthetic heart valves. Nosocomial endocarditis is increasingly common; the source is often infected intravascular devices, pacemakers, and hemodialysis catheters.

Most patients with bacterial endocarditis have a predisposing valvular abnormality. Among older patients, calcific or degenerative disease of the aortic and mitral valves is the most common predisposing factor. Rheumatic heart disease (RHD), although less prevalent than in prior decades, remains an important predisposing factor for IE among individuals from developing countries. Congenital cardiac lesions involving high-pressure gradients (e.g., ventricular septal defects, pulmonary stenosis, tetralogy of Fallot) also increase the risk of IE. The history of previous endocarditis is a major risk factor for recurrence because infected valves heal with irregularities that become a nidus for future vegetations. Mitral valve prolapse (MVP) is now the most common predisposing abnormality for IE in developed countries.

The incidence of IE associated with injection drug use is estimated at 150 to 2000/100,000 person-years. Although any valve can be affected, injection drug use is typically associated with right-sided endocarditis.

Prosthetic valve endocarditis (PVE) is a unique and potentially devastating complication of valve replacement. The incidence of endocarditis in prosthetic valve recipients ranges from 0.5% to 4%/year. PVE can arise early or late after surgery, and the timing of infection reflects different portals of entry and microbiology.

The hospital mortality rate for IE is high, with many centers reporting a mortality rate of around 20% and with rates varying according to the proportion of causative microorganism and presence of complications.1,5 Viridans streptococci and Streptococcus bovis carry a mortality of less than 10%, but the mortality is more than 40% in patients with prosthetic valve IE due to Staphylococcus aureus. The mortality for right-sided endocarditis resulting from injection drug use is approximately 10%.

Pathophysiology

The classic lesion of endocarditis is the vegetation, originating as a sterile thrombus on which microorganisms adhere and colonize. The target is usually the cardiac valve; however, chordae tendineae, septal defects, and the endocardium can be involved. The initial thrombus may form at a site of mechanical damage induced by inflammation, degenerative changes, or abnormal turbulence. In injection drug users, contaminants such as talc can injure the previously normal valve leaflets and encourage bacterial implantation. Theoretically, the onset of bacterial endocarditis is preceded by a period of subclinical bacteremia. Dental procedures, cystoscopy, endoscopy, and other invasive procedures result in transient bacteremia, but usually there is no clear precipitant for community-acquired IE.

A number of microorganisms cause IE, with staphylococci and streptococci accounting for most cases (Table 73.1). Although many organisms cause IE, a few have such a predilection that they count as a major criterion in the modified Duke score (Box 73.1). A blood culture positive for community-acquired enterococcus and Streptococcus bovis should suggest IE. Also, the HACEK group—Haemophilus spp., Aggregatibacter actinomycetemcomitans, Cardiobacterium hominis, Eikenella corrodens, and Kingella kingae—a collection of fastidious gram-negative bacilli, is commonly reported in large studies of IE. Finally, a positive blood culture or positive antibody titer to Coxiella burnetii (Q fever) is also included in the modified Duke score.

The microbiology of PVE relates to the time of onset. S. aureus is now the most prevalent pathogen in the first 2 months after valve replacement, followed by coagulase-negative staphylococci. One year after surgery, the microbiology mirrors native valve endocarditis. Among injection drug users, the most common infecting organism is S. aureus, often causing right-sided infections.

Candida and Aspergillus spp. cause most cases of fungal endocarditis. Predisposing factors include indwelling intravenous (IV) catheters, immunocompromise, and injection drug use. Large fungal vegetations can embolize, and analysis of these emboli may be the only clue suggesting fungal endocarditis. Bartonella spp. is another group of fastidious organisms associated with IE in immunocompromised patients.

CLINICAL FEATURES AND DIFFERENTIAL DIAGNOSIS

Symptoms associated with IE are nonspecific and diverse. The most common symptoms are intermittent fever (85%) and

Duke Criteria (Clinical) for Diagnosis of Infective Endocarditis

DEFINITE ENDOCARDITIS
Endocarditis is considered definitely present if any one of the following combinations of clinical findings is present:
- Two major clinical criteria
- One major and any three minor clinical criteria
- Five minor clinical criteria

POSSIBLE ENDOCARDITIS
Possible endocarditis is defined as the presence of any one of the following combinations of clinical findings:
- One major and one or two minor clinical criteria
- Three minor clinical criteria

REJECTED ENDOCARDITIS
The diagnosis of endocarditis is considered rejected if any of the following occurs:
- A firm alternate diagnosis is made.
- Resolution of clinical manifestations occurs after 4 days or less of antibiotic therapy.
- Clinical criteria for possible or definite infective endocarditis not met.

MAJOR CRITERIA
Positive blood cultures (of typical pathogens) from at least two separate cultures
Evidence of endocardial involvement by echocardiography, such as the following:
- Endocardial vegetation
- Paravalvular abscess
- New partial dehiscence of prosthetic valve
- New valvular regurgitation

MINOR CRITERIA
Predisposition—predisposing heart condition or intravenous drug use
Fever—temperature > 38°C (100.4°F)
Vascular phenomena—arterial emboli, septic pulmonary infarcts, mycotic aneurysm, conjunctival hemorrhages, or Janeway lesions
Immunologic phenomena—Osler’s nodes, Roth’s spots, and rheumatoid factor
Microbiologic evidence—single positive blood culture (except for coagulase-negative Staphylococcus or an organism that does not cause endocarditis)
Echocardiographic findings—consistent with endocarditis but do not meet major criteria

Infective Endocarditis, Rheumatic Fever, and Valvular Heart Disease

Malaise (80%). Other nonspecific symptoms (eg, weakness, myalgias, back pain, dyspnea, chest pain, cough, headaches, anorexia) vary widely in their incidence. Many patients seen early during the bacteremic phase of the illness do not have a cardiac murmur and are indistinguishable from the large population of patients who come to the emergency department (ED) with a febrile viral illness. During the initial assessment, a careful history should be taken, with attention to any preexisting cardiac pathology or clues suggesting a recent source of bacteremia, such as IV drug use, indwelling intravascular catheters, or invasive procedures. In the absence of specific risk factors, the diagnosis of IE may be suspected when infectious symptoms persist or do not follow a typical course for viremia. The classic triad of fever, anemia, and heart murmur is rare.

Some patients will have complications of IE as presenting complaints. The most common and severe are congestive heart failure and neurologic events. Heart failure results from valvular destruction. A patient with stoke-like symptoms and fever should alert one to the possibility of IE. Strokes can be the result of septic emboli or ruptured mycotic aneurysms.

Almost all patients with IE have a cardiac murmur at some time during the course of their illness. A murmur, however, may be absent at presentation. In this population, unexplained fever alone is sufficient to raise concern about possible endocarditis. A substantial minority of patients exhibit some form of vasculitic lesion, including petechiae, splinter hemorrhages, Osler’s nodes, and Janeway lesions. Approximately 30% of patients have splenomegaly. Ocular findings include conjunctival or retinal hemorrhages, the latter of which may have a characteristic pale center surrounded by a red halo (Roth’s spots).

DIAGNOSTIC TESTING
Laboratory findings in bacterial endocarditis are nonspecific. As with other infectious conditions, leukocytosis is insensitive (occurring in <50% of patients diagnosed with IE) and nonspecific. An elevated erythrocyte sedimentation rate or C-reactive protein level may be present, but these are also nonspecific. Most patients have a mild anemia, and up to 50% have microscopic hematuria as a result of embolic lesions of the kidney. A chest radiograph may show signs of heart failure or embolic disease, and an electrocardiogram (ECG) may display conduction abnormalities if an abscess has formed in the myocardium.

Although not always practical, three blood cultures from three separate venipuncture sites are recommended for patients with a presumptive diagnosis of possible endocarditis, with the first and last cultures preferably drawn 1 hour apart. If the patient appears septic, cultures may be obtained more rapidly to permit initiation of early empirical therapy. Cultures need not be timed to the presence of chills or fever because patients with IE typically have a continuous bacteremia.

Echocardiography should be performed in all patients for whom the suspicion of endocarditis is moderate to high. Although transthoracic echocardiography (TTE) is highly specific for vegetations in IE, it may be nondiagnostic because of obesity, chronic obstructive pulmonary disease, and chest wall deformities. Overall
sensitivity of TTE is at most 60%. Transesophageal echocardiography (TEE), on the other hand, although more invasive and time-consuming, is far superior to TTE in its sensitivity and specificity.

Explicit criteria for the diagnosis of IE are important because underdiagnosis can lead to serious morbidity and death, whereas overdiagnosis can result in weeks of unnecessary antimicrobial therapy. The modified Duke criteria are the most widely accepted and validated, stratifying patients with suspected bacterial endocarditis into three distinct categories—definite, possible, and rejected (Box 73.1).6

MANAGEMENT

Once the diagnosis of IE is established, whether by clinical, echocardiographic, or microbiologic methods, antimicrobial therapy should be administered. The choice of antibiotics depends on the likely (or known) causative organism but is usually empirical. In the ED, however, usually without results of an echocardiogram (TTE or TEE), the diagnosis of endocarditis is not confirmed. In addition, there is increasing concern regarding community-acquired, methicillin-resistant S. aureus (MRSA), even in native valve endocarditis. Thus, a combination of 15 mg/kg of vancomycin and 2 g of ceftriaxone is a reasonable empirical antibiotic choice in someone with undifferentiated sepsis and suspected endocarditis.

Endocarditis is a heterogeneous disease. Although initial treatment is medical, early consultation with a cardiac surgeon is advisable when mechanical complications are observed or expected (eg, in patients with acute heart failure or those with infections involving prosthetic valves; Box 73.2). Consultation with an infectious diseases specialist or cardiologist is also useful. Early valve replacement for more severe disease may decrease the risk of embolic events.7 If possible, most patients with left-sided endocarditis should be initially managed in facilities with access to cardiac surgery.

With appropriate antibiotic therapy, most patients with IE will defervesce within 1 week. The duration of antibiotic therapy needs to be sufficient to eradicate microorganisms present within the valvular vegetation. This may require 6 weeks, or more, depending on the organism and type of vegetation.5

DISPOSITION

Historically, most patients with IE received the entire course of antimicrobial therapy while in the hospital. The development of home health care, however, allows selected patients with endocarditis to be treated as outpatients during much or all of their therapy. Patients selected for outpatient therapy should be hemodynamically stable, compliant, and capable of managing the technical aspects of IV therapy.

PROPHYLAXIS

The American Heart Association guidelines limit prophylaxis to conditions with the highest risk of adverse outcome from IE (Box 73.3).7 Virtually all the procedures that are routinely performed in the ED, including suturing of lacerations, endotracheal intubation, placement of central venous catheters, vaginal deliveries, and placement of Foley catheters (in the absence of infection), do not require prophylactic antibiotics.

RHEUMATIC FEVER

PRINCIPLES

Background and Importance

From 1920 to 1950, acute rheumatic fever (ARF) was the leading cause of death in US children and the most common cause of heart disease in individuals younger than age 40 years. During the 1960s and 1970s, the incidence of ARF in the United States and other developed countries declined dramatically because of widespread antibiotic treatment of streptococcal infections, declining prevalence of the more virulent strains of group A streptococi, and improved living conditions. Children 4 to 9 years of age remain at greatest risk, with an incidence of ARF of 2 to 14 cases/100,000. In many developing nations, however, ARF continues to be a leading cause of childhood mortality. RHD peaks in adults between the ages of 25 and 34 years and continues to be a leading cause of morbidity and mortality in impoverished areas.10

Pathophysiology

ARF is a delayed nonsuppurative complication of streptococcal pharyngitis. Although the pathogenesis remains obscure, ARF results from an exaggerated immunologic response to group A beta-hemolytic streptococci that results in antibodies cross-reacting with tissues in the heart, joints, skin, and central nervous system. Patients with a history of ARF are predisposed to recurrent infections, and repeated infections lead to progressive heart damage.

CLINICAL FEATURES AND DIFFERENTIAL DIAGNOSIS

Acute rheumatic fever occurs approximately 3 weeks after the initial bout of pharyngitis (ranging from 1–5 weeks). Up to one-third of patients with documented ARF do not remember having had pharyngitis in the preceding month. Fever is generally present during the acute phase of rheumatic fever, rarely lasting more

BOX 73.2

Conditions Requiring Surgical Therapy for Infective Endocarditis

- Infective endocarditis with acute heart failure
- Fungal endocarditis
- Periannular extension of infection
- Recurrent emboli
- Large mobile vegetations
- Persistent bacteremia

BOX 73.3

High-Risk Conditions for Bacterial Endocarditis

- Prosthetic heart valve
- History of endocarditis
- Unrepaired cyanotic congenital heart disease, including palliative shunts and conduits
- Completely repaired congenital heart defects with prosthesis during the first 6 mo after the procedure
- Repaired congenital heart disease with residual defect at or adjacent to the site of the prosthetic device
- Cardiac valvulopathy in a transplanted heart
than 2 weeks without a characteristic pattern. Along with fever, manifestations of ARF may include arthritis, carditis, chorea, subcutaneous nodules, and erythema marginatum.

Migratory polyarthritis is the most common manifestation of ARF. Arthritis tends to occur early in the course of ARF and often coincides with a rising titer of streptococcal antibodies. The polyarthritis classically affects larger joints, such as the knees, ankles, elbows, and wrists, and the pain can be more severe than physical findings suggest. Analysis of the synovial fluid generally reveals a sterile inflammatory fluid.

Cardiac manifestations of ARF may be subtle and can include symptoms and signs of pericarditis, myocarditis, and endocarditis. The mitral valve is the most common valve affected in ARF, causing mitral regurgitation. Inflammation of the valvar endocardium can result in permanent deformity and impairment of one or more cardiac valves over the course of decades. Stenotic lesions of the mitral or aortic valves are unusual at presentation, but are common late manifestations of RHD (Fig. 73.1).

Chorea is manifested by random, rapid, purposeless movements, usually of the upper extremities and face. Chorea is relatively rare in ARF and tends to emerge after a longer latency period than some of the other manifestations. Erythema marginatum and subcutaneous nodules are found in fewer than 10% of cases of ARF. Their presence, however, should suggest the diagnosis. Erythema marginatum is a nonpruritic, painless, evanescent so-called smoke ring of erythema that commonly appears on the trunk and proximal extremities (Fig. 73.2). Subcutaneous nodules are pea-sized and nontender. They typically appear over the extensor surfaces of the wrists, elbows, knees and, occasionally, the spine.

**DIAGNOSTIC TESTING**

In 1944, Jones formulated major and minor criteria for the diagnosis of ARF. After multiple revisions, the Jones criteria remain the diagnostic basis for this disease (Box 73.4). The diagnosis of ARF necessitates evidence of an antecedent streptococcal infection plus at least two major, or one major and two minor, manifestations from the Jones criteria. Although throat cultures are usually negative at the time of clinical onset of ARF, antistreptolysin

**BOX 73.4**

**Jones Criteria (Revised) for the Diagnosis of Acute Rheumatic Fever**

**MAJOR MANIFESTATIONS**
- Carditis
- Polyarthritis
- Chorea
- Erythema marginatum
- Subcutaneous nodules

**MINOR MANIFESTATIONS**
- Arthralgias
- Fever
- Increased erythrocyte sedimentation rate or C-reactive protein level
- Prolonged PR interval

**EVIDENCE OF PRECEDING STREPTOCOCCAL INFECTION**
- Positive throat culture for group A beta-hemolytic streptococci or positive rapid streptococcal antigen test
- Elevated or rising streptococcal antibody titer, usually antistreptolysin O

**Fig. 73.1.** Transthoracic echocardiography of symptomatic rheumatic mitral stenosis (* represents a thickened anterior mitral leaflet). Ao, Aorta; LA, left atrium; LV, left ventricle; RV, right ventricle. (From Marijon E, et al.: Rheumatic heart disease. Lancet 379:953–964, 2012.)

**Fig. 73.2.** Erythema marginatum. This is one form of annular erythema seen in 10% of cases of children with acute rheumatic fever but is rare in adults with the disease. (From Cohen J, Powderly WG: Infectious diseases, ed 2, New York, 2004, Mosby.)
antibody titers remain positive for 4 to 6 weeks from the time of infection. The erythrocyte sedimentation rate and C-reactive protein levels are typically elevated, and a prolonged PR interval is common and suggestive in ARF.

MANAGEMENT AND DISPOSITION

All patients with ARF should receive antibiotic therapy, regardless of the clinical history of pharyngitis. Penicillin can be administered orally (250 mg for children, 500 mg for adults, bid or tid for 10 days) or intramuscularly (600,000 units of benzathine penicillin in patients weighing <27 kg and 1.2 million units in patients >27 kg as a one-time dose).

Treatment for arthritis consists of antiinflammatory agents, usually aspirin, administered until symptoms are absent and the erythrocyte sedimentation rate and C-reactive protein concentration normalize. Patients with severe carditis are often treated with corticosteroids, but no evidence supports this treatment. Patients with congestive heart failure should be managed accordingly. Treatment of patients with ARF involves only symptom relief and does not decrease the likelihood of progression to RHD. Primary prevention involves treating those with group A streptococcal pharyngitis within 9 days of the onset of symptoms because this greatly decreases the risk of ARF. Patients with a history of ARF should receive ongoing prophylactic antibiotics (generally, penicillin) to prevent recurrences. The recommended duration of secondary prophylaxis varies, depending on the presence and severity of cardiac involvement.

VALVULAR HEART DISEASE

PRINCIPLES

Anatomy and Physiology

Of the four heart valves, three (tricuspid, pulmonic, and aortic) are composed of three cusps, whereas the mitral valve has only two cusps. Each cusp is a double layer of endocardium attached at its base to the fibrous skeleton of the heart. The margins of the cusps are attached to muscular projections from the ventricles (papillary muscles) via tendinous cords (chordae tendineae). Contraction of the ventricle, and consequently the papillary muscle, results in the opening or closing of the valve, depending on its location.

Mitral Stenosis

The most common cause of mitral stenosis is RHD. Symptoms of valvular dysfunction typically develop after a latency period of 1 to 3 decades. Many patients will not recall a history of ARF. Less common causes of mitral stenosis include congenital mitral stenosis and mitral annular calcification.

Pathophysiology

The normal cross-sectional area of the mitral valve orifice is 4 to 6 cm². Stenosis becomes clinically significant when the area decreases to below 2 cm². Impeded flow from the left atrium to the left ventricle results in left atrial hypertension, restricted cardiac output, and, ultimately, pulmonary congestion. As the disease progresses, patients may develop pulmonary hypertension and right ventricular failure.

The most common complication of mitral stenosis is atrial fibrillation, which, in the absence of rate control, is not well tolerated. Patients with underlying mitral stenosis will decompensate under other conditions associated with increased cardiac demand and reduced ventricular filling, such as pregnancy, anemia, infection, and hyperthyroidism.

Clinical Features

Early symptoms of mitral stenosis include reduced exercise tolerance and dyspnea on exertion. Patients with more advanced disease may have orthopnea and, if right ventricular failure is present, peripheral edema. Hemoptyis, caused by the rupture of a bronchial vein, and hoarseness, caused by compression of the recurrent laryngeal nerve, are classic but uncommon presentations. Aside from the typical signs of heart failure, findings that suggest the presence of mitral stenosis include a loud S₃ and an opening snap in early diastole, accompanied by a low-pitched, rumbling diastolic apical murmur.

Although the chest radiograph may be normal, left atrial enlargement may be suggested by straightening of the left heart border in more advanced cases. Common electrocardiographic abnormalities, in addition to atrial fibrillation, include left atrial enlargement and, ultimately, right ventricular hypertrophy. Echo-cardiography confirms the diagnosis and assesses the severity of disease.

Management

Medical treatment for patients with mitral stenosis is comprised of diuresis for symptoms of vascular congestion and anticoagulation for atrial fibrillation. Once symptoms have developed, however, median survival without intervention is 7 years. Several surgical options exist, ranging from balloon valvulotomy or open commissurotomy to valve reconstruction or replacement. Management of the patient with mitral stenosis in the ED centers on identification and treatment of underlying precipitants, such as atrial fibrillation or anemia, diuresis, and referral for definitive intervention.

Mitral Regurgitation

Acute and chronic mitral regurgitation are two distinct disease entities. Acute mitral regurgitation is a true emergency. It can result from idiopathic rupture of the chordae tendineae, papillary muscle dysfunction in the setting of acute ischemia, papillary muscle rupture 2 to 7 days postinfarction, or perforation of a valve leaflet in the setting of infectious endocarditis or trauma. Chronic mitral regurgitation, on the other hand, usually occurs in the setting of dilated cardiomyopathy (due to enlargement of the mitral annular ring) or RHD, often coexisting with mitral stenosis. Other causes of chronic mitral regurgitation include MVP and connective tissue disorders, such as Marfan syndrome and Ehlers-Danlos syndrome.

Pathophysiology

Acute mitral regurgitation is associated with low left atrial compliance and thus sharply elevated left atrial pressure, which results in acute pulmonary congestion. In contrast, chronic mitral regurgitation is characterized by high left atrial compliance and near-normal left atrial pressures, with reduced forward output. Patients with chronic mitral regurgitation typically decompensate in the setting of volume overload.

Clinical Features

The characteristic presentation of acute mitral regurgitation is one of fulminant pulmonary edema. This is accompanied by a unique, harsh, mid-systolic murmur that radiates to the base rather than the axilla. Patients typically have no prior history of heart failure. The ECG may display signs of ischemia or infarction.

The presentation of chronic mitral regurgitation is similar to that of chronic systolic heart failure, with clinical symptoms and
signs of decompensated congestion. The murmur is classically described as holosystolic, heard best at the apex and radiating to the axilla. The ECG often reflects left atrial and ventricular hypertrophy. Atrial fibrillation is common, and left atrial enlargement may be suggested by the chest radiograph. Echocardiography may demonstrate a normal or above-normal ejection fraction, but some portion of systolic flow is retrograde.

Management
When the diagnosis of acute mitral regurgitation is suspected, emergency echocardiography and cardiac catheterization will assess the degree of regurgitation and urgency for surgery. Initial stabilization should include treatment of pulmonary edema with nitrates and diuretics. In a hypotensive patient, a counterpulsation intraaortic balloon pump may provide temporary stabilization as a bridge to surgery.

The natural history of chronic mitral regurgitation is generally a very slow progression, with 15-year survival approaching 70% with medical therapy, including diuretics and afterload-reducing agents. However, once the ejection fraction falls below 60%, valve repair or replacement is recommended to avoid irreversible left ventricular dysfunction.13

Aortic Stenosis
The most common cause of aortic stenosis is calcific degeneration, which is prevalent in older adults with coronary artery disease. This also occurs in younger individuals with a bicuspid aortic valve. Aortic stenosis can also coexist with mitral stenosis in patients with RHD.

Pathophysiology
The normal aortic valve area is larger than 3 cm². Significant obstruction occurs when the valve area is reduced by more than 50%. Critical aortic stenosis is defined by a valve area of less than 0.8 cm² or a pressure gradient across the valve that exceeds 50 mm Hg. Compensatory left ventricular hypertrophy can maintain cardiac output until the stenosis becomes severe. Further progression of disease is associated with left ventricular dysfunction, left atrial enlargement, and atrial fibrillation. Individuals with severe or critical aortic stenosis are preload-dependent and have very little cardiovascular reserve. Any disruption of the delicate balance between myocardial oxygen supply and demand (eg, rapid atrial fibrillation, dehydration, acute blood loss) can result in precipitous decompensation.

Clinical Features
Classic symptoms of aortic stenosis progress from angina (increased demand resulting from wall stress and decreased supply resulting from reduction in perfusion pressure) to exertional syncope (fixed cardiac output and vasodepressor response), to congestive heart failure (diastolic and ultimately systolic dysfunction). In an older patient with chest pain, particularly if seemingly preload-dependent, the possibility of aortic stenosis, with or without coronary artery disease, should be considered.

The classic auscultatory finding in aortic stenosis is a crescendo-decrescendo systolic murmur heard best at the base (right second intercostal space) that radiates into the carotids and is associated with the presence of an S4 gallop and a soft aortic component of S2. Although counterintuitive, as the severity of disease increases, the murmur peaks later and becomes less apparent. Carotid pulses may be delayed (tardus) and diminished in intensity (parvus). The ECG typically reveals left ventricular hypertrophy. Echocardiography is required for the assessment of the severity of stenosis and presence of left ventricular dysfunction.

Aortic Insufficiency
Aortic insufficiency can occur as a consequence of RHD, infectioous endocarditis, or the presence of a bicuspid valve. Aortic root abnormalities, such as ectasia, aneurysm, or dissection, can also lead to aortic insufficiency.

Pathophysiology
In acute aortic insufficiency, left ventricular compliance is low, and left ventricular pressure increases rapidly during diastole, leading to acute pulmonary congestion. In chronic aortic insufficiency, the left ventricle dilates, allowing the heart to maintain normal or near-normal cardiac output, despite significant regurgitation. The enhanced stroke volume results in a wide pulse pressure and the clinical signs that are commonly associated with aortic insufficiency. Pulmonary congestion, when present, is generally a consequence of volume overload.

Clinical Features
Patients with acute aortic insufficiency can present with severe respiratory distress and/or frank cardiogenic shock. At the same time, the physical findings specific to acute aortic insufficiency can be quite subtle. The pulse pressure will be widened only slightly, if at all, and the short, soft, diastolic murmur may be difficult to detect. Emergent echocardiography is required to confirm the diagnosis.

In contrast, chronic aortic insufficiency is characterized by a widened pulse pressure, which may be accompanied by a number of classic physical findings, such as a rapidly rising and falling carotid pulse (water hammer, or Corrigan’s pulse), spontaneous nail bed pulsations (Quincke’s sign), or a to and fro murmur over the femoral artery (Duroziez’s sign). A high-pitched, blowing, diastolic murmur at the left sternal border is characteristic of chronic aortic insufficiency. An Austin-Flint murmur—the soft diastolic rumble caused by a regurgitant stream against the mitral valve—may also be present.

Management
In contrast to chronic aortic insufficiency, acute aortic insufficiency is a surgical emergency necessitating urgent valve replacement, along with repair of any underlying aortic root pathology. Medical stabilization entails the cautious use of vasodilators and diuretics. For obvious reasons, intraaortic balloon counterpulsulation is contraindicated in the presence of an incompetent aortic valve. Chronic aortic insufficiency is managed like other types of decompensated heart failure, with emphasis on diuresis, as well as preload and afterload reduction. Ideally, however, valve repair or replacement should be performed before the development of left ventricular systolic dysfunction.13
Mitral Valve Prolapse

MVP is defined pathophysiologically as an abnormal movement of one or both of the mitral valve leaflets during systole. Although generally a benign condition, it is infrequently associated with more serious cardiac pathology such as mitral regurgitation, endocarditis, and arrhythmias. Echocardiographic studies report a true prevalence of less than 1% in men and women versus the previously reported 5%, with a female predominance.  

Pathophysiology

Structurally, MVP is characterized by myxomatous proliferation of the spongiosa layer within the mitral valve that results in abnormal billowing of the leaflet during systole. MVP usually occurs in isolation but, like other valvular diseases, may be associated with other connective tissue disorders, such as Marfan syndrome and Ehlers-Danlos syndrome.

Clinical Features

MVP is associated with a wide variety of clinical symptoms, including chest pain, palpitations, dyspnea, lightheadedness, and fatigue. Appropriately controlled clinical studies, however, such as the Framingham Heart Study, have suggested that patients with MVP and control subjects may be equally symptomatic. The classic auscultatory feature of MVP is a midsystolic click caused by snapping of the chordae tendineae with prolapse of the valve. Occasionally a mid to late systolic murmur can be appreciated over the mitral area. Confirmation of the diagnosis is made by echocardiography.

Management

Cardioselective beta blockers may control symptoms such as palpitations, chest pain, and anxiety. Lifestyle modifications, such as exercise, relaxation techniques, and avoidance of ethanol or caffeine and other stimulants, may also be helpful. Often, simple reassurance about the generally benign nature of the disease will suffice.

Complications of Prosthetic Valves

Prosthetic heart valves are classified as mechanical or biologic. The latter category includes whole valve transplants (human or porcine) as well as bioprosthetic valves, which are typically manufactured from bovine pericardium. All prosthetic heart valves are associated with complications, ranging from structural failure and thrombosis to systemic embolization, hemolysis, and endocarditis. In the acute setting, the diagnosis of a prosthetic valve complication can be challenging because symptoms and signs are often subtle.

Primary structural failure is extremely uncommon with modern mechanical valves. When it does occur, the presentation is one of acute severe regurgitation and shock, and emergent valve replacement is required. With biologic valves, in contrast, structural failure is relatively more common, but less dramatic. At 10 years, 20% to 30% of bioprosthetic valves exhibit some evidence of structural failure, and most are replaced electively. Symptoms are characteristically insidious in onset and are similar to those of native valvular disease.

Prosthetic valve thrombosis occurs with mechanical and biologic valves. When adequately anticoagulated, mechanical valves have thrombotic complications at a similar rate (≈2%/year) as biologic valves. Symptoms of prosthetic valve thrombosis are generally subacute and may have characteristics of stenotic disease, regurgitant disease, or both. On physical examination, the diagnosis is suggested by a decreased or absent valve click, new regurgitant murmur, or louder than expected stenotic murmur. Echocardiography may demonstrate the thrombus or restricted leaflet motion. Treatment options include fibrinolytic therapy and surgery.

The incidence of systemic embolization from a prosthetic valve is approximately 1%/year. Compared with aortic valve prostheses, mitral valve prostheses are associated with twice the risk of systemic embolization, with rates roughly equal for a biologic mitral valve or appropriately anticoagulated mechanical mitral valve. The vast majority of diagnosed embolic events (85%) involve the central nervous system, and roughly 50% of these result in permanent impairment.

A mild hemolytic anemia resulting from sheer forces through the prosthetic valve aperture is common but usually subclinical. In more severe cases, presenting features can include dyspnea, fatigue, and even jaundice. Iron replacement is effective therapy for most patients but transfusion may be required in severe cases. If hemolysis is the result of a periprosthetic leak or other structural failure, scheduled reoperation is commonly required.

The incidence of PVE is highest during the initial months after surgery and is similar for mechanical and bioprosthetic valves. Early PVE, within 60 days of surgery, is presumed to be caused by a pathogen acquired perioperatively and is associated with higher morbidity and mortality, whereas late PVE is more likely related to transient bacteremia and is generally associated with a more benign course. As with other forms of endocarditis, fever is the most common presenting symptom, whereas other manifestations are variable. Echocardiography can identify vegetations, but a normal study does not rule out endocarditis. In the ED, the diagnosis of PVE is generally presumptive because definitive diagnosis requires blood cultures or biopsy.

KEY CONCEPTS

- Many patients seen early in the bacteremic phase of IE lack a murmur and are indistinguishable from those with viremia.
- Patients for whom suspicion of endocarditis is moderate to high require blood cultures, echocardiography, and admission for definitive diagnosis and initiation of empirical therapy.
- Prophylaxis for IE is rarely, if ever, indicated for procedures performed in the ED.
- Acute rheumatic fever is a delayed nonsuppurative complication of streptococcal pharyngitis characterized by arthritis, carditis, chorea, subcutaneous nodules, and erythema marginatum.
- In a patient with severe mitral stenosis, hypovolemia and tachycardia are poorly tolerated. Slow and full are appropriate goals.
- In patients with critical aortic stenosis, excessive preload reduction with vasodilators and diuretics is to be avoided.
- In patients with acute aortic insufficiency, classic physical findings may be absent. Medical stabilization entails the cautious use of vasodilators and diuretics. Intraaortic balloon counterpulsation is contraindicated.
- Complications of prosthetic heart valves range from structural failure and thrombosis to systemic embolization, hemolysis, and endocarditis.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
73.1. What is the most common manifestation of acute rheumatic fever (ARF)?
A. Carditis
B. Chorea
C. Erythema marginatum
D. Polyarthritis
E. Subcutaneous nodules

Answer: D. Arthritis occurs early in the course of ARF. The knees, ankles, elbows, and wrists are commonly affected, and pain can be out of proportion to physical findings. Cardiac manifestations are subtle and may reflect endocarditis, myocardiitis, or pericarditis. Chorea, nodules, and erythema marginatum are rare. Chorea is typically a late finding.

73.2. A 49-year-old woman presents with progressive dyspnea on exertion and orthopnea. Vital signs are temperature 36.7°C (98.1°F; oral), heart rate, 110 beats/min, blood pressure, 135/80 mm Hg, respiratory rate, 22 breaths/min, and oxygen (O₂) saturation, 97% on room air. The physical examination is remarkable for clear lung fields and an irregularly irregular rhythm with a 4/6 diastolic murmur in the left anterior axillary line. She has no peripheral edema. Which of the following would be appropriate hemodynamic management of her cardiac pathophysiology?
A. Aggressive diuresis
B. β₁-Agonist to increase chronotropy
C. Beta blockade
D. Selective arterial vasodilator
E. Selective venodilator

Answer: C. This patient has a picture consistent with atrial fibrillation and mitral stenosis. The apical diastolic murmur and left atrial enlargement, along with progressive dyspnea, all support the diagnosis. Tachycardia is poorly tolerated because of the need for higher left atrial pressures and a longer time during diastole to perfuse across the stenotic valve. Slow and full would be appropriate guidelines. Both diuresis and a venodilator might decrease venous return. Any agent producing tachycardia would decrease diastolic time and left ventricular preload. An arterial vasodilator would have little effect, given the normal blood pressure and the fact that systemic vascular dilation would not be seen at the mitral valve level as long as the aortic valve was competent.
Hypertension (HTN) is an important but largely treatable risk factor for cardiovascular disease that affects almost one-third of Americans and approximately 1 billion people worldwide. Although more than 80% of those with HTN are aware of their condition and most (~75%) are receiving at least some form of antihypertensive therapy, blood pressure (BP) remains uncontrolled in nearly 50% of patients. The implications of this on the practice of emergency medicine are clear. According to data from a nationwide emergency department (ED) sample between 2006 and 2010, one of every five ED visits included HTN as a diagnosis. Moreover, as shown in the most recent analysis of the National Hospital Ambulatory Medical Care Survey, moderate (ie, >140–159/90–99 mm Hg) to severely elevated (ie, ≥160/100 mm Hg) BP is present in over 40% of ED patients.

Despite this understanding, there is a critical divide between what constitutes emergency and medicine when it comes to elevated BP in the ED. When associated with acute target organ damage (TOD), HTN represents a true emergency that warrants emergent intervention. However, this is relatively rare and, for the vast majority, acute TOD will be not be present, even in the setting of markedly elevated BP. Although such patients have a low likelihood of near-term adverse events and are thus not emergencies per se, they would undoubtedly benefit from measures to decrease their overall cardiovascular risk through better BP control. This distinction is thus a key aspect of the approach to HTN in the ED and a core feature of emergency medicine practice.

Importance

Hypertension is a major modifiable risk factor for the development of cardiovascular, cerebrovascular, and renovascular disease. Uncontrolled BP is strongly associated with heart failure, myocardial infarction, stroke, vascular dementia, and chronic kidney disease. The risk of developing these conditions increases with the degree of BP elevation, and it has been estimated that the risk of cardiovascular disease doubles for each elevation of 20 mm Hg systolic and 10 mm Hg diastolic BP, starting at 115/75 mm Hg. Conversely, BP treatment can lower the risk for stroke by 40%, myocardial infarction by 25%, and heart failure by 50%.

The distribution of HTN is not uniform. African Americans have higher rates of disease (40.4% vs. 27.1% for whites) and poorer BP control, leading to an increased risk of adverse outcome, whereas people of Hispanic ethnicity have lower rates (26%). This disparity, in combination with other economic, social, and lifestyle determinants, leads to dramatically increased morbidity of cardiovascular disease in the African American population. HTN is the single most important contributor to racial differences in life-years lost from cardiovascular disease, accounting for 50% of the excess risk within the African American community.

Definition of Hypertension and Relevant Terminology

Although BP below 120/80 mm Hg is considered normal, an understanding of what constitutes HTN has been evolving. Present definitions are based on the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7), which set a BP level of 120 to 139/80 to 89 mm Hg as pre-HTN, 140 to 159/90 to 99 mm Hg as stage I HTN, and 160/100 mm Hg or higher as stage II HTN. In the JNC 8, a much anticipated update to this pivotal guideline, no changes to these categorical definitions were proposed. However, greater emphasis was placed on age-based treatment thresholds, with antihypertensive therapy recommended when the systolic BP exceeds 140 mm Hg for those younger than 60 years and 150 mm Hg for those 60 years of age or older. As with other guidelines, a diastolic BP of 90 mm Hg or higher remains an indication for treatment, regardless of age.

Historically, the approach to BP measurement has been office-based, with a diagnosis of HTN considered to be present when BP of 140/90 mm Hg or higher is detected on properly measured, seated readings on two or more occasions. Recent data have suggested that 24-hour ambulatory BP measurement may be a better method for establishing a diagnosis of HTN. Ambulatory BP measurement enables the evaluation of BP over a range of conditions, minimizing the potential for so-called white coat effects while increasing the likelihood of detecting masked HTN. The increased reliability of the ambulatory BP measurement has prompted recent guidelines to recommend that the threshold for HTN be set at 135/85 mm Hg when the BP is determined via this approach.

How ED-measured BPs fit into this paradigm is not clear. Many ED patients with elevated BP will have an established history of HTN, but a sizeable proportion will not, presenting an opportunity to establish the diagnosis. Although this should be approached with caution on the basis of a single ED measurement, demonstration of persistently elevated BP over several prior ED visits may be a reasonable indicator of true underlying HTN. Prior studies have shown that as many as 70% of patients with elevated BP in the ED will also have an abnormal BP at primary care follow-up, and this proportion increases with the ED BP value. Newer automated BP devices that perform serial measurements, discarding the first reading and averaging subsequent
values, have been shown to improve the accuracy of office-based methods and may be a useful adjunct in the ED for such patients.\textsuperscript{19}

Perhaps more important in the ED setting than making the diagnosis of chronic HTN is understanding the need for acute intervention among patients who have marked BP elevations (ie, \( \geq 180/100 \text{ mm Hg} \)). Although terms such as hypertensive crisis, hypertensive urgency, and accelerated or malignant HTN, are liberally applied to such patients, they are poorly defined and are often used interchangeably and incorrectly by emergency clinicians. A better approach focuses on the presence (or absence) of signs or symptoms attributable to acute TOD within the context of established or potentially new-onset HTN, thus distinguishing patients with active vasculopathy from those without.

Based on this conceptual model, there are three distinct subgroups of patients with elevated BP that are relevant to emergency medicine practice:

1. **Hypertensive emergency**—a disease state defined by acute TOD, manifest by newly developed clinical sequelae or diagnostic test abnormalities. A hypertensive emergency can exist in patients with or without underlying chronic HTN. Although it has been estimated that 1% to 2% of patients with chronic HTN will experience a hypertensive emergency in their lifetime, hospitalization for this condition is relatively rare, occurring in only 110 of every 100,000 admissions in the United States.\textsuperscript{20}

2. **Poorly controlled chronic HTN**—a presentation in which patients with established HTN are found to have elevated BP without specific attributable symptoms or evidence of acute TOD. Such presentations often result from nonadherence to treatment regimens or inadequate medical management, but may also reflect refractory disease. Concurrent use of seemingly innocuous medications, including nonsteroidal anti-inflammatory drugs (NSAIDs), steroids, decongestants, appetite suppressants, over-the-counter stimulants, oral contraceptives, and tricyclic antidepressants or rebound from short-acting antihypertensives, such as clonidine, may be contributory.

3. **Elevated BP without prior history of HTN**—a relatively frequent occurrence in which routine ED vital signs identify an elevated BP. Such individuals also may visit the ED after an outpatient physical examination, community health screening event, or self-performed, automated BP measurement identifies elevated BP. Whether or not this truly represents HTN can be difficult to determine in the ED, and all such patients should have repeat measurement of BP, ideally 1 hour or more after arrival, and after analgesic treatment for those with acute pain. Depending on the circumstance, an evaluation for potential TOD may be warranted, along with referral for subsequent follow-up in an outpatient setting.

An approach to elevated BP in the ED based on this understanding is presented in Fig. 74.1.

**Physiology of Hypertension**

Whereas BP is known to rise with increasing age, onset of HTN in the non–older adults represents a complex interplay of multiple inciting factors, including neurohormonal dysregulation, vascular modulation, sodium intake, psychosocial stress, and obesity. Alterations in cardiac and renal function are also important, serving as contributors to and consequences of ongoing BP elevation. Despite an advanced understanding of the pathophysiology of HTN, the definitive cause of elevated BP remains unknown in more than 90% of patients. These individuals are labeled as having primary or essential HTN, and the cause is considered idiopathic. In the subset of patients for whom an identifiable cause can be ascertained, the term secondary HTN applies (Table 74.1). Although it may not be possible to diagnose and treat such causes of secondary HTN in the ED, when suspected, early referral for outpatient evaluation or, in some cases, hospital admission to expedite evaluation, may be warranted.

**Neurohormonal Dysregulation**

The sympathetic nervous system (SNS) has a pivotal role in the development of HTN.\textsuperscript{21} Norepinephrine, the principal sympathetic neurotransmitter, is a potent stimulator of vasoconstriction. This effect is mediated through peripheral \( \alpha \)-adrenergic receptor activation in vascular smooth muscle cells and occurs predominantly in small-diameter arterioles. Although individually these vessels contribute a miniscule amount to BP, in aggregate they serve as the primary driver of systemic vascular resistance (SVR) and constitute the main force that amplifies afterload in HTN.\textsuperscript{22} The SNS also stimulates \( \beta \)-adrenergic receptors in the heart, leading to an increase in cardiac output (CO) through augmentation of stroke volume and heart rate, but these are considered lesser contributors to the pathologic process of high BP. Sympathoactivation exerts additional direct effects on the kidney that promote sodium reabsorption, leading to an increase in circulating blood volume, and trigger renin release, resulting in angiotensin II production and further vasoconstriction.\textsuperscript{23}

In addition to activation by the SNS, the renin-angiotensin-aldosterone system exerts critical independent effects on BP.\textsuperscript{24,25} Renin is an enzyme produced by juxtaglomerular cells in the kidney in response to several factors beyond adrenergic stimulation, including sodium load in the distal tubule and renal perfusion status. Renin cleaves angiotensin I from its plasma globulin precursor, angiotensinogen. Angiotensin I is then converted to
**Sodium Intake**

The average American has a daily sodium intake of close to 3500 mg (150 mEq)—more than double the recommended level of 1500 mg (≈65 mEq) recommended by the American Heart Association (AHA) in its 2011 guidelines. Randomized trials have demonstrated a reduction in systolic BP with diminished daily sodium intake (up to 7 mm Hg/1200 mg, or a 52-mEq decrease in hypertensive individuals); however, the impact of this intervention on long-term cardiovascular outcomes is unclear.

Salt sensitivity is defined by an increase in BP with intake of a high-sodium diet. It is linked to obesity but may be more directly related to defects in renal ion transport mechanisms that lead to ongoing sodium retention and potassium depletion. Although not fully defined, the latter plays a critical role, because the entire effect of salt sensitivity on BP can be mitigated with high-dose potassium supplementation.

**Psychosocial Stress**

Life stressors, especially socioeconomic status, are known to affect health and wellness adversely. Through its effects on SNS function and the hypothalamic-pituitary axis, stress modulates BP and is a

**Angiotensin II**

Angiotensin II by circulating and tissue-bound (especially in the lung), angiotensin-converting enzyme (ACE). Angiotensin II exerts systemic and renal effects by binding to angiotensin II type I (AT₁) receptors, which results in arterial vasoconstriction, sodium reabsorption, and modulation of the glomerular filtration rate (GFR). Through AT₁ receptor binding in the adrenal gland, angiotensin II also serves as a potent stimulator of aldosterone release, which promotes further sodium reabsorption and potassium excretion.

**Vascular Modulation**

Continued vascular stimulation by the SNS and renin-angiotensin-aldosterone system, coupled with an increase in wall tension caused by HTN itself, leads to ongoing remodeling throughout the arterial tree. In large vessels such as the aorta or carotid arteries, this results in increasing intima-media thickness, with minimal luminal narrowing—unless there is unrelated plaque buildup. In contrast, small-vessel and arteriolar remodeling reduce the lumen diameter. Although both forms of remodeling work to normalize wall stress associated with HTN, they reduce vasodilatory capacity and enhance the vasoconstrictor response when faced with a hypertensive stimulus.

---

**Sodium Intake**

The average American has a daily sodium intake of close to 3500 mg (150 mEq)—more than double the recommended level of 1500 mg (≈65 mEq) recommended by the American Heart Association (AHA) in its 2011 guidelines. Randomized trials have demonstrated a reduction in systolic BP with diminished daily sodium intake (up to 7 mm Hg/1200 mg, or a 52-mEq decrease in hypertensive individuals); however, the impact of this intervention on long-term cardiovascular outcomes is unclear. Salt sensitivity is defined by an increase in BP with intake of a high-sodium diet. It is linked to obesity but may be more directly related to defects in renal ion transport mechanisms that lead to ongoing sodium retention and potassium depletion. Although not fully defined, the latter plays a critical role, because the entire effect of salt sensitivity on BP can be mitigated with high-dose potassium supplementation.

**Psychosocial Stress**

Life stressors, especially socioeconomic status, are known to affect health and wellness adversely. Through its effects on SNS function and the hypothalamic-pituitary axis, stress modulates BP and is a
specific contributor to disparities in HTN. Although episodic stress reactions can lead to transient sympathetic surges, sustained stimulation related to ongoing concern over life circumstances (e.g., financial security, crime and safety, racism) triggers a chronic adaptive response and has been emerging as an important consideration in patients with seemingly idiopathic HTN.

**Obesity**

Obesity is a known risk factor for the development of HTN. For every increase of body mass index by 5 kg/m², the risk of hypertension increases by 1.4 (95% confidence interval [CI], 1.38–1.49). Elevated BP in obese individuals correlates with high circulating aldosterone and cortisol levels, which in turn may be related to salt sensitivity. Obesity, especially truncal, is also strongly associated with diabetes and obstructive sleep apnea, both of which contribute to poor BP control.

**Pathophysiology of Target-Organ Damage**

Uninterrupted by treatment, continued vasoconstriction in chronic HTN leads to a number of deleterious consequences that culminate in TOD. On a macrocirculatory level, the central components of the cardiovascular system (i.e., heart, large blood vessels) are most affected. Sustained elevations in SVR cause significant augmentation of the pressure wave reflected from the periphery back to the central circulation (termed the augmentation index), thus driving left ventricular (LV) afterload; the increase manifests with a rise in the central aortic pressure and change in the morphology of its waveform. This results in increasing impedance to forward flow from the heart, which in turn necessitates greater contractile force to maintain aortic valve opening and the duration of ventricular ejection. Active contraction against this resistance also increases intraventricular wall tension, which, together with ongoing stimulation from, among other things, the SNS and renin-angiotensin-aldosterone system, triggers cardiomyocyte hypertrophy and myocardial fibrosis. Initially, this leads to an increase in LV mass, which enhances the heart’s pumping against excessive afterload. However, when progressive, the net result is LV stiffening and impaired diastolic function, with an increase in LV filling pressure and diminished flow from the left atrium to the left ventricle. If the increase in afterload is sudden, an abrupt decrease in stroke volume occurs, precipitating backflow of fluid into the lungs and rapid onset of so-called flash pulmonary edema. If excess afterload is more gradual or even chronic, a subacute rise in LV end-diastolic pressure may cause increased wall tension, with compression of the subendocardial microvasculature and myocardial ischemia. Over time, this contributes to LV wall thickening, chamber dilation, and eventually systolic dysfunction.

On a microcirculatory level, the initial beneficial effect of vascular remodeling gradually gives way to critical luminal narrowing and the potential for regional ischemia from occlusion or loss of vessel wall integrity with leakage or rupture. Autoregulation, the intrinsic capacity of resistance vessels to dilate or constrict rapidly in response to dynamic perfusion pressure changes, works to maintain relatively constant blood flow and is protective with moderate fluctuations. Small-vessel ischemic episodes, many of which are silent, are the primary cause of chronic TOD, including progressive white matter (i.e., multi-infarct) disease in the brain and hypertensive nephropathy. Cerebral microbleeds, which are identified by imaging of hemosiderin deposits on brain magnetic resonance imaging (MRI) scans, are a relatively new class of subclinical brain injury associated with chronic HTN and portend more rapid cognitive decline in older adults.

Unlike the pattern of TOD that occurs with poorly controlled chronic HTN, a hypertensive emergency results from acute endothelial injury triggered by an abrupt rise in vascular pressure that overwhelms autoregulatory mechanisms. A subsequent drop in nitric oxide (NO)–mediated vascular smooth muscle relaxation and excess release of endothelin further increase SVR, which functionally maintains BP at severely elevated levels. Unchecked wall tension ensues, and terminal arterioles dilate and eventually rupture, leading to a proinflammatory hypercoagulable state, with fibrin deposition and diffuse ischemia. Rising pressure in the proximal capillary beds causes fluid leakage and tissue edema, which, combined with the process of fibrinoid necrosis, produces acute TOD along with microangiopathic hemolytic anemia and other signs of small vessel injury.

**CLINICAL FEATURES**

Although BP elevation alone does not define any particular clinical syndrome, acute TOD does not occur in the absence of moderate to severe HTN (i.e., ≥180/110 mm Hg). Conversely, in the absence of symptoms, the mere presence of an excessively high BP in the ED (regardless of the level) does not herald imminent development of TOD.

**Hypertensive Emergency**

Most hypertensive emergencies occur in patients with chronic HTN. Organ system involvement is relatively consistent and is dominated by injury to the heart, brain, or kidneys (Table 74.2). True hypertensive emergencies are defined by the target organ acutely involved. Focal neurologic deficit or altered mentation point to brain injury, whereas chest pain or shortness of breath may be indicative of cardiac or vascular involvement. Although frequently accompanied by an elevated BP, symptoms such as headache, epistaxis, and dizziness are not, in and of themselves, evidence of acute TOD and, in isolation, do not constitute a hypertensive emergency nor do they indicate the need for acute BP reduction.

Hypertensive Encephalopathy

Hypertensive encephalopathy is the essential factor in hypertensive emergencies. Resulting from diffuse, vasogenic cerebral edema, it is caused by a failure of autoregulation in the brain, with vasospasm, ischemia, increased vascular permeability, punctate hemorrhages, and interstitial edema. Severe headache, vomiting, and altered mental status are common features, which may progress to seizures or coma. Retinal involvement may cause blurred vision progressing to complete blindness. When present, focal neurologic deficits do not follow a singular anatomic pattern and may occur on opposite sides of the body, indicating diffuse cerebral dysfunction rather than an anatomically localized stroke syndrome or space-occupying lesions. Papilledema, although difficult to recognize, is often present, along with significant hypertensive retinopathy. Computed tomography (CT) may not show acute hemorrhage or other acute pathology. Diffuse or regional cerebral edema and small hemorrhages have been reported. The combination of diffuse cerebral dysfunction on clinical examination, normal or nonspecific CT scan, and markedly elevated systemic BP, particularly if supported by objective findings such as papilledema or retinal hemorrhage, is sufficient to make a presumptive diagnosis of hypertensive emergency and necessitates the initiation of acute antihypertensive therapy. Hypertensive encephalopathy is fully reversible with early, prompt BP reduction (30%–40% decrease); recently published data from the Nationwide Inpatient Sample have suggested that the overall in-hospital mortality rate is less than 1%.37

First defined in 1996, posterior reversible encephalopathy syndrome (PRES) has a neurologic presentation similar to that of hypertensive encephalopathy, albeit with less global and more region-specific features. Also caused by increased vascular permeability secondary to endothelial damage with vasogenic edema, PRES is characterized by a constellation of symptoms related to posterior cerebral impairment, including visual changes, headache, altered mental status, and seizures.3 It is diagnosed by the visualization of white matter edema in the posterior parieto-temporal-occipital regions on MRI. As the name suggests, PRES is reversible by treating the underlying cause. HTN is the most common condition associated with PRES, although it may also be seen with kidney disease, malignancies, cytotoxic therapy, and autoimmune disease.

Other Hypertension-Related Emergencies

The clinical features of other hypertension-related emergencies cross over with nonhypertensive manifestations, and they are described in greater detail elsewhere in this text. Moreover, these conditions are defined by more than just HTN and, in many cases, their onset is incidental to, not caused by, elevated BP. However, long-standing HTN is often a contributor to the underlying problem and, when elevated BP is causal, effective treatment can have a dramatic impact on the clinical course. Elevated BP frequently accompanies acute intracranial hemorrhage, and the rapid initiation of antihypertensive therapy is a routine component of ED care (see Chapter 91). HTN is the primary population-attributable risk factor for the development of chronic cardiac dysfunction, and more than 50% of ED patients with acute heart failure have elevated BP on presentation (see Chapter 71). Patients with acute heart failure and HTN respond well to vasodilatory agents and afterload reduction. Nitroglycerin has long been used in the setting of acute coronary syndrome and demand ischemia (see Chapter 68), and antihypertensive therapy is a key component of ED management for acute aortic dissection (see Chapter 73). Acute kidney injury in the setting of elevated BP may be a consequence of associated TOD, especially acute heart failure, particularly when these patients are on baseline diuretic or calcium channel blocker therapy. Recent or chronic NSAID or newly initiated ACE inhibitor therapy may also contribute, but the effect of these agents are usually transient (see Chapter 87).34 Pre-eclampsia and eclampsia are discussed in Chapter 178.

Blood Pressure Elevation

Acute Target Organ Damage in the Context of Systemic Illness

Any medical condition that leads to a hypermetabolic state can impair electrolyte homeostasis and trigger an intrinsic vasomotor response, causing BP to rise acutely. Depending on the circumstance, this may also be associated with clinical or diagnostic evidence of acute TOD. Distinguishing this from a true hypertensive emergency necessitates demonstration that the elevated BP does not contribute directly to the pathologic condition. Treatment of the underlying disorder will often resolve the BP elevation, although BP reduction may play a role in supportive management.

Absence of Target Organ Dysfunction

Most patients who are found to have significant HTN on intake vital signs measurement or who come to the ED because BP was found to be elevated in an outpatient setting or by self-measurement do not have an acute hypertensive emergency. For such patients, acute reduction of BP is not indicated and offers no tangible outcome benefit. Although many patients who fall into this group have poorly controlled chronic HTN, some will lack such a history. To connote an absence of acute TOD, these patients are often described by the term asymptomatic, but this is potentially misleading because nonspecific symptoms (eg, low-grade or recurrent headache, atypical chest pain, dyspnea, dizziness, generalized weakness, focal but anatomically uncorrelated weakness or numbness, vague visual disturbances) are frequently present. However, with the exception of dyspnea, the occurrence of these symptoms appears to be unrelated to the degree of BP elevation. In addition, despite widespread belief among the lay community and some members of the health care profession that acute severe HTN contributes to epistaxis, there is no evidence to support a causal relationship.33

As a general rule, acute BP reduction is not indicated in patients with elevated BP who lack acute TOD, even when vague symptoms are present. In many cases, BP will spontaneously improve with time, and there is no need to hasten this with antihypertensive therapy. If chronic oral medications have been missed, as is often the case, these should be restarted, perhaps with the first dose administered in the ED to reinforce the importance of future compliance, although this is in no way required and will not change any outcome. However, there are no data supporting a threshold BP that warrants such treatment or a target BP to be achieved before discharge. Importantly, the administration of a short-acting, potent antihypertensive agent such as clonidine or hydralazine simply to improve BP values lacks rationale or evidence of benefit and, according to a retrospective cohort study, may be associated with an increased likelihood of subsequent ED visit for issues related to HTN.34 As previous experience with sublingual nifedipine has shown, BP reduction in the absence of acute TOD is also potentially dangerous, inducing relative cerebral hypoperfusion and increasing the likelihood of related morbidity and mortality, and should not be administered in the ED.

DIAGNOSTIC CONSIDERATIONS

Differential Diagnoses

Differential considerations are based on patient subtype. For those with a suspected hypertensive emergency, the decision point
centers on the potential causal relationship between patient presentation and acutely elevated BP. Clinical entities within this broader heading, such as stroke syndromes and acute heart failure, carry their own differentials, but a full discussion of each is beyond the scope of this chapter. Depending on the clinical scenario, ancillary testing may be needed to rule out alternatives to a hypertensive cause, particularly in patients with systemic illness. For those with poorly controlled chronic HTN, a consideration of cause (ie, primary vs. secondary) may be warranted. A related diagnostic evaluation (see Table 74.1) can usually be pursued on an outpatient basis, but for some (ie, individuals with multiple episodes of flash pulmonary edema, symptomatic paroxysmal episodes of labile BP, or suspected poor follow-up), initiation of treatment from the ED or admission to the hospital is needed. The final factor to consider is whether a newly detected BP elevation is caused by true HTN. Although the diagnostic accuracy of BP can be enhanced by a second repeat measurement in the ED, the ideal approach may be to average several measurements taken over a brief period of observation. For those without a previous history of HTN, definitive diagnosis will typically require reassessment in an outpatient setting.

**Diagnostic Testing**

The diagnostic evaluation of hypertensive emergency is guided by symptoms and signs identified on clinical examination but will often involve a number of tests. In nearly all cases, laboratory testing to look for acute or worsening renal dysfunction (ie, basic metabolic panel, urinalysis) and microangiopathic hemolytic anemia (ie, complete blood count with manual differential, peripheral smear) may be needed. Individuals with chest pain or shortness of breath may require a chest radiograph, electrocardiogram, and cardiac biomarker (ie, troponin, natriuretic peptide [NP]) measurement. Advanced cardiovascular imaging by CT, transesophageal echocardiography, or MRI should be considered if there is clinical suspicion for aortic dissection. When focal neurologic deficits or altered mentation is present, nonenhanced brain imaging by CT and, in many cases, MRI, will be needed, along with laboratory tests to evaluate for potential toxic, metabolic, or infectious causes.

Hypertensive retinopathy identified on funduscopy signifies underlying TOD and, when present, is strongly associated with an enhanced risk of stroke in patients with HTN.49 Findings of acute hypertensive retinopathy include focal intraretinal periarteriolar transudates (whitish ovoid lesions deep in the retina), focal retinal pigment epithelial lesions (evidence of choroidal injury), macular and optic disk edema, and cotton wool spots (fluffy white lesions that consist of swollen ischemic axons caused by small vessel occlusion). Hard exudates, which consist of lipid deposits located deep in the retina, are also a common but late occurrence. When identified, such funduscopic abnormalities are considered diagnostic; however, they may be absent in more than 30% of patients with a clinically evident hypertensive emergency.50 Lesions of acute retinopathy are distinct from more chronic changes, which include arterial narrowing, copper or silver wiring of the arterioles, arteriovenous nicking, and retinal hemorrhages. The spectrum of retinal findings in HTN can be graded on a five-point scale (Box 74.1). Despite such value, funduscopia is infrequently performed in the evaluation of severely elevated BP in ED patients. Technical challenges and a lack of experience likely contribute to this. Nonmydriatic digital fundus photography can help overcome these issues and has shown promise as an adjunct to detect chronic and acute changes associated with hypertensive retinopathy in the ED setting.57

</tbody>
</table>

Although funduscopia provides useful information, whether this or any other form of diagnostic evaluation is needed in the ED for those without overt TOD is a matter of debate. Although the JNC 7 has provided recommendations on routine testing in the primary care setting, there is no specific guidance for the ED.53 In the only prospective multicenter study of JNC 7–recommended routine tests (ie, basic metabolic panel, urinalysis, electrocardiography, chest x-ray) performed in the ED, clinically meaningful abnormalities were detected in only 6% of patients, none of which were definitively attributable to HTN. However, in settings where HTN-related kidney disease is prevalent (eg, predominantly African American communities), evaluation of renal function by a basic metabolic panel may be a reasonable consideration. Although such information is highly unlikely to affect emergent management, there is value in knowing baseline renal function and electrolyte levels, particularly if the initiation of chronic antihypertensive therapy is planned. Urine testing, especially spot measurement of the urine albumin-to-creatinine (Cr) ratio, is a reasonable alternative to detect subclinical kidney disease, although it does not provide information on electrolyte levels.9 Newer markers of renal dysfunction, including cystatin C, neutrophil gelatinase–associated lipocalin, and kidney injury molecule–1, may also be considered, but their availability in most medical centers is limited,60 and they are not indicated for an emergent evaluation. Unlike renal function, there is no simple, efficient test for detecting subclinical cardiac disease in the ED, and evaluation in this setting is guided by symptoms. Although chest x-ray and electrocardiography are often used, they have poor sensitivity for TOD (especially LV hypertrophy), and abnormalities, when identified, are unlikely to alter clinical management.51 Serum NP levels (ie, B-type NP [BNP] and N-terminal pro-BNP [NT-proBNP]) have yielded conflicting results and are not optimal screening tests, nor are they indicated for the emergent evaluation of HTN unless there is suspected cardiac TOD. Based on findings from a recent study in which echocardiography was used as the criterion standard, the prevalence of subclinical hypertensive heart disease in select populations appears to be substantial (=90%), suggesting the need for development of a more effective screening strategy.52 Bedside cardiac ultrasound in the ED focused on the identification of LV hypertrophy and perhaps diastolic dysfunction has shown potential for this purpose;53,54 however, validation of such an approach in large prospective trials will be needed before widespread adoption can be endorsed.

**MANAGEMENT**

**Acute Blood Pressure Control**

**Antihypertensive Therapy**

Antihypertensive therapy is indicated in treatment of acute hypertensive encephalopathy and in the presence of specific target organ injury (see earlier). The goal of acute antihypertensive therapy is to lower BP safely and effectively in a relatively rapid fashion while maintaining peripheral perfusion. Although some oral (ie, clonidine) or sublingual (ie, captopril, nitroglycerin)
medications are capable of this, patients who truly require acute lowering of BP benefit from the predictable controlled effects of a parenteral agent by titrated intravenous (IV) boluses or by adjustable infusion.

Mean arterial pressure (MAP), a summary measure that represents the average arterial pressure during one cardiac cycle, is a composite of circulatory inputs. The relationship is defined by the following equation:

\[
\text{MAP} = (\text{CO} \times \text{SVR}) + \text{CVP}
\]

where SVR reflects vasogenic tone in the arterioles (ie, afterload), CO reflects the pumping force of the heart, and central venous pressure (CVP) represents intravascular volume (ie, preload) and the effective hydrostatic force in the circulatory system. The hemodynamic response to a specific medication or class of medications is a function of how they interact with this equation and, as shown in Table 74.3, effects can differ substantially. Existing IV antihypertensive agents exert their effects directly through receptor-mediated actions (largely agonist or antagonist properties) or indirectly through a decrease in the production or release of endogenous vasoconstrictors. The magnitude of BP reduction reflects the mechanism of action as well as the pharmacokinetic and pharmacodynamic activity, with some variability in the latter based on aging.

According to the STAT (Studying the Treatment of Acute hyperTension) registry, labetalol and nitroglycerin are the most common IV antihypertensive medications used in the ED, but outcome data related to different agents are lacking. Thus, although studies such as CLUE (Evaluation of IV Nicardipine and Labetalol Use in the Emergency Department) have suggested more favorable effects on BP reduction with nicardipine, a dihydropyridine calcium channel blocker, clear superiority of one drug over another has yet to be demonstrated. A general guide to IV antihypertensive therapy is provided in Table 74.4. However, depending on the desired response profile, certain agents may be more appealing than others for a specific indication.

### Blood Pressure Goals

Optimal treatment of a true hypertensive emergency involves therapy that is directed toward the precipitant of specific TOD and the acute consequences of elevated BP rather than the BP itself. Based on recommendations in JNC 7, the long-standing approach to acute antihypertensive therapy has been to target a maximal reduction in MAP of 20% to 25% within the first hour and a goal BP of 160/100 mm Hg by 2 to 6 hours. This arises from an understanding of the cerebral autoregulation curve, which maintains stable blood flow within a range of pressures (MAP of 60–160 mm Hg) under normal circumstances, but resets in chronic HTN with a shift of the lower limit toward the right. This shift tends to settle at a point approximately 25% below baseline MAP, resulting in concern for a decrease cerebral blood flow with BP reduction beyond this. Although such a consideration is relevant for patients who have poorly controlled chronic HTN, BP is often markedly elevated compared with baseline and well above the lower limit of the individual patient’s autoregulation curve in the setting of a hypertensive emergency. Consequently, a margin of safety exists in this case, with antihypertensive therapy serving to bring BP down to (rather than along) the perfusion plateau from the ascending portion of the autoregulation curve (Fig. 74.2). Use of a single BP goal for all hypertensive emergencies fails to account for this and may preclude the ability to interrupt the pathophysiology causing acute TOD effectively. Therefore, the best approach is to focus on condition-specific targets. An overview of respective treatment goals and relevant caveats for differing indications is found in Table 74.5.

### Acute Coronary Syndrome and Acute Heart Failure

In acute coronary syndrome complicated by HTN, the primary goal (beyond expeditious reperfusion) is a decrease in cardiac work and improved coronary artery perfusion, each of which can be dramatically affected by changes in afterload. Similarly, in

improving systolic ejection time and diastolic coronary artery filling.

Rapid reduction in MAP has been associated with profound symptom resolution and improved short-term outcomes among patients with severe, acute hypertensive heart failure. As shown in Fig. 74.3, this may be due to improved coronary perfusion and a decrease in subendocardial ischemia. Achieving this may require higher doses of nitroglycerin than most emergency clinicians are accustomed to (ie, 1–2 mg by bolus or infusion rates greater than 250 µg/min), but this approach appears to be well tolerated, with

patients with acute hypertensive heart failure, in which a rise in SVR—more specifically the augmentation index—impedes forward flow and exacerbates ventricular stiffness, intervention aimed at reducing afterload can offset resistive forces, enabling more effective contraction. Nitric oxide (NO) donors (medications that exert their effect by providing an exogenous source of NO), such as nitroglycerin, can be highly beneficial in both circumstances because they produce small-vessel dilation, which yields a dose-dependent decrease in overall vascular resistance, and diminish the intensity of arterial waveform reflection, thus

Because they produce a decrease in CO and, in acute coronary metoprolol, should be avoided in the early stages of treatment and other IV agents with inhibitory

With aortic dissection, unlike for other hypertensive emergencies, no adverse effects, even at MAP reductions of 30% to 40%. Moreover, using nitroglycerin in this manner avoids the challenges associated with alternatives such as sodium nitroprusside, including the need for arterial line monitoring, risk of cyanide toxicity, and potential for compound photodegradation. Perhaps the only caveat is that NO donors should be used with caution in patients who have taken a phosphodiesterase-5 (PDE5) inhibitor such as sildenafil (Viagra) or tadalafil (Cialis) within the preceding 24 to 48 hours because this can result in more a profound BP decrease and persistent hypotension.

ACE inhibitors are also well tolerated and have been associated with rapid symptom improvement in patients with hypertensive heart failure. Enalaprilat can be administered by IV bolus or infusion and is the preferred ACE inhibitor in the setting of acute heart failure, but cautious dosages (0.625–1.25 mg/dose, up to a maximum of 2.5 mg over 30 minutes) are recommended because the drug is long-acting and can precipitate a sustained drop in BP. Given their short half-life, third- and fourth-generation IV dihydropyridine calcium channel blockers (eg, nicardipine, clevidipine) have been emerging as potential alternatives, with at least one prospective trial suggesting that this class can safely and effectively reduce BP while improving dyspnea more rapidly than standard therapy in those with acute hypertensive heart failure. Labetalol and other IV agents with inhibitory β-adrenergic effects, such as metoprolol, should be avoided in the early stages of treatment because they produce a decrease in CO and, in acute coronary syndrome, may increase the risk of developing cardiogenic shock.

Although BP reduction drives symptom improvement in acute hypertensive heart failure, adverse events are more likely to occur when BP is rapidly normalized (ie, decreased to ≤120/80 mm Hg), particularly in the setting of compromised cardiac function. Therefore, antihypertensive therapy for acute coronary syndrome or acute heart failure should be titrated to symptom resolution rather than a specific MAP, with short-term tolerance of persistently elevated BP in a clinically improving patient.

Aortic Dissection

With aortic dissection, unlike for other hypertensive emergencies, BP control to a specific target (systolic BP < 110 mm Hg) is essential because it decreases ongoing injury and reduces the likelihood of perioperative adverse events. The immediate goal is to reduce intimal shear forces by driving down the pressure that results from LV ejection with each cardiac cycle (termed dP/dt). This is best accomplished by decreasing heart rate and stroke volume through administration of a rapid-acting IV beta blocker, such as esmolol. Although a direct reduction in BP is also critical, it is important that beta blocker therapy be initiated before vasodilation because the latter can lead to reflex tachycardia and worsening of dP/dt. Once beta blockers have been initiated, and a heart rate of less than 60 beats/min has been achieved, agents such as sodium nitroprusside, nicardipine, or clevidipine can be rapidly titrated to reduce systolic BP as low as can be tolerated (and, ideally, to <120 mm Hg) within 30 minutes. Because labetalol has both alpha and beta blocker properties, it may be an acceptable alternative, particularly if used as a continuous infusion. Diltiazem and verapamil, which are both mixed calcium channel blockers (ie, agents with cardiac and vascular effects), may also be used, although neither is ideal as monotherapy. For patients with persistently elevated BP, despite initial therapy, the use of multiple agents from different classes may be needed.

Acute Ischemic Stroke

Understanding the nuances of elevated BP in acute ischemic stroke is critical. A U-shaped relationship exists between mortality and BP, with worse outcomes at the high and low extremes. The optimal range appears to lie between 120 and 200 mm Hg systolic, and 81 to 110 mm Hg diastolic, but consensus on a specific target or threshold for treatment is lacking. Current American Heart Association/American Stroke Association (AHA/ASA) guidelines call for a BP reduction to below 185/110 mm Hg only when thrombolysis is planned, with maintenance of BP at below 180/110 in such cases. Otherwise, antihypertensive therapy is not indicated unless BP is higher than 220/120 mm Hg and, even in such cases, the goal is to decrease BP by approximately 15% gradually, over the first 24 hours after symptom onset. The AHA/ASA guidelines are supported by a metaregression of BP control trials in stroke that suggest the following: (1) an association between large rises or falls in BP and worse outcome; and (2) a decrease in death and/or dependency with more modest BP reduction.

Based on these recommendations, and considering data from two large randomized studies (Scandinavian Candesartan Acute Stroke Trial [SCAST]; N = 2,099, a double-blind randomized controlled trial in Acute Ischemic Stroke [CATIS]; N = 4071), that showed no benefit with BP reduction over the first 24 hours, there appears to be a limited role for ED management of elevated BP in patients with acute ischemic stroke who will not undergo thrombolysis. However, a subanalysis of SCAST also showed a trend toward reduced vascular events (but not functional outcomes) among those treated within 6 hours of symptom onset, suggesting a possible time-dependent component, with increased susceptibility to the adverse effects of sustained BP elevation earlier in the disease course.

For patients who need IV antihypertensive therapy, labetalol and nicardipine have emerged as the agents of choice because they maintain adequate cerebral perfusion while producing generalized reductions in vascular resistance. Nicardipine may offer some advantage over labetalol because it results in a more rapid and sustained achievement of BP goals with reduced BP variability, a potentially important determinant of patient outcome. Esmolol may also be used, although its BP effects depend more on a reduction in CO than systemic vascular resistance. Although sodium nitroprusside is a highly effective antihypertensive option, it and other NO donors should be avoided because they can cause an increase in intracranial pressure.
Spontaneous Intracranial Hemorrhage

Spontaneous intracranial hemorrhage (ICH) is strongly associated with HTN, and persistently elevated BP contributes to hematoma expansion, vasogenic edema, and rebleeding. A large systematic review and several multicenter trials have shown improved outcomes with BP reductions to 140 to 150 mm Hg. In contrast to ischemic stroke, there is little evidence to suggest adverse outcomes from hypotension in ICH. The 2010 AHA/ASA guidelines recommended rapid reduction when the systolic BP exceeds 200 mm Hg or MAP exceeds 150 mm Hg and stated that a target systolic BP of 140 mm Hg is safe for such patients. When more modest elevations are present (systolic BP > 180 mm Hg or MAP > 130 mm Hg), lower targets are indicated (BP, 160/90 mm Hg, or MAP, 110 mm Hg).

Although reasonably informative, these guidelines were developed based on incomplete efficacy data that included limited information on the ideal time to achieve BP targets. Results from the recent SPRINT trial suggest that intensive antihypertensive therapy targeting a systolic BP of 140 mm Hg within 1 hour may improve outcomes for patients with a baseline systolic BP between 150 and 220 mm Hg, although no difference in mortality or major disability was found. However, in a recent post hoc analysis of INTERACT2, patients who achieved a reduction in systolic BP of 20 mm Hg or more within the first hour of treatment (N = 1092) were 35% less likely to experience a poor outcome, suggesting that optimal recovery from acute ICH requires early, intensive antihypertensive therapy. Data from the Antihypertensive Treatment of Cerebral Hemorrhage (ATACH II) study (NCT01176565), which has enrolled 1280 patients and has included an intervention arm of target systolic BP lower than 140 mm Hg within 4.5 hours.

*Nitric oxide donors and hydralazine should be avoided with these indications. BP, Blood pressure; dP/dt, change in pressure/change in time; FDA, US Food and Drug Administration. Adapted from Levy P. Hypertensive emergencies: on the cutting edge. Advancing the standard of care: cardiovascular and neurovascular emergencies. www.emreg.org.
discretion and urapidil, an α-adrenergic antagonist, was the most commonly used agent (32.5%) in the intensive treatment arm, followed by nitroglycerin or nitroprusside (27.0%), nicardipine (16.2%), and labetalol (14.4%). Whether such heterogeneity in antihypertensive therapy may have influenced outcomes is not known, making the pending ATACH-II study, in which nicardipine of ICH onset, will have provided much needed additional insight into the timing and intensity of BP control in this patient population.

As with ischemic stroke, labetalol and nicardipine are the preferred agents for acute BP reduction. However, in INTERACT2, the choice of antihypertensive therapy was at emergency clinician discretion. Fig. 74.3. Serial electrocardiograms demonstrating resolution of relative myocardial ischemia in a profoundly hypertensive patient with acute heart failure after treatment with high-dose intravenous nitroglycerin. **A**, BP, 241/122 mm Hg. Anterior leads (V1–3) show ST segment elevation and lateral leads (V5–6) show ST depression. **B**, BP, 192/103 mm Hg. Anterior lead ST elevation has resolved, but lateral lead ST depressions persist. **C**, BP, 150/92 mm Hg. ST segment deviations have largely resolved.
is being used exclusively, all the more important. Nimodipine, an oral dihydropyridine calcium channel blocker, is specifically indicated for patients with subarachnoid hemorrhage, although its benefit appears to be related more to a reduction in intracranial arterial vasospasm than to an effect on SVR.

Hypertensive Encephalopathy

Unlike acute stroke syndromes, in which HTN may be reactive rather than causative, a direct association exists between the degree of BP elevation and neurologic symptoms in patients with hypertensive encephalopathy. Once alternative causes of altered mentation have been ruled out, therapy should be directed toward the initiation of rapid BP reduction. The goal is to return BP to a point at which autoregulation can regain control of cerebral blood flow and the process leading to cerebral edema can be reversed—a circumstance that necessitates MAP to be brought back down to the pressure curve plateau. To achieve this, reductions in MAP of 30% to 40% may be needed. Whereas MAP targets should still be kept in mind, symptom resolution is the best gauge of therapeutic effectiveness, with treatment directed specifically toward improvement of encephalopathy.

The agents of choice for BP reduction in hypertensive encephalopathy are labetalol and nicardipine because they produce an even decrease in resistance across vascular beds in different organ systems. In contrast, NO donors (nitroglycerin and nitroprusside), although widely used for this indication, have a differential effect on the cerebral and systemic circulations, resulting in a relative increase in cerebral BP and a shunt effect to the peripheral circulation. This serves to decrease cerebral blood flow and may produce a greater than anticipated reduction in cerebral perfusion, thereby increasing the risk of ischemia in watershed areas of the brain. This may be worsened by the relative increase in intracranial pressure known to occur with sodium nitroprusside therapy. Several case reports have described neurologic deterioration with administration of nitroglycerin in posterior reversible encephalopathy syndrome (PRES), a subtype of hypertensive encephalopathy, supporting this as an actual rather than theoretical concern. Similar differential circulatory effects may also occur with hydralazine (a direct-acting vasodilator that inhibits calcium release from the sarcoplasmic reticulum) and, unless BP is completely refractory to other therapy, it is best to avoid use of these agents.

Acute Kidney Injury

Defined by an increase in serum creatinine level of 0.3 mg/dL or more in 48 hours, 1.5 or more times baseline in 7 days, or a urine volume of less than 0.5 ml/kg/hr over 6 hours, acute kidney injury (AKI) represents an abrupt worsening of renal function. Although often a manifestation of ongoing glomerular injury from chronic poor BP control, deterioration of kidney function in the setting of severe HTN may be precipitated by prerenal causes, including volume depletion (often related to concurrent diuretic therapy), extrinsic alterations in the GFR (often triggered by drug-mediated, afferent arteriolar vasoconstriction and ACE inhibitor–induced autoregulatory modulation) or intrinsic nephron destruction caused by acute pressure overload. Consequently, some patients require fluid administration to augment volume, whereas others need antihypertensive therapy to mitigate pressure-mediated nephrogenic damage.

Laboratory testing is useful to differentiate which approach should be initiated. A blood urea nitrogen (BUN)/Cr ratio higher than 20 and a fractional excretion of sodium (FENa); calculated as below 1%—or for those on chronic diuretic therapy, a fractional excretion of urea (FEurea); calculated as

\[
\text{Serum Cr} \times \frac{\text{Urine urea}}{100} = \frac{\text{Serum urea}}{\text{Urine Cr}}
\]

below 35%—serve as indicators of a prerenal cause.

When antihypertensive therapy is indicated, fenoldopam, a potent dopamine 1A receptor agonist, is preferred because it leads to improved perfusion of the corticomedullary region and has been associated with a reduction in need for subsequent dialysis and rate of in-hospital death. Enalaprilat should be avoided because it produces differential effects on the precapillary and postcapillary glomerular vascular bed (ie, greater vasodilation in afferent than efferent arterioles), which increases the risk of further deterioration in estimated GFR. Peripheral-acting calcium channel blockers, such as clevidipine and nicardipine, have no adverse effect on glomerular autoregulation and are acceptable first-line alternatives to fenoldopam. Other agents, including labetalol and sodium nitroprusside, may also be used.

Preeclampsia and Eclampsia

Although delivery is the definitive treatment, BP control is a critical part of early management. Similar to hypertensive encephalopathy, preeclampsia and, to a greater degree, eclampsia, represent an overwhelming of cerebral autoregulation, and rapid BP reduction is essential. Because they are acute (rather than chronic) complications in a relatively healthy young population, there is generally no resetting of the autoregulation curve in preeclampsia or eclampsia, and adverse consequences can develop at seemingly “low” (but relatively high) pressures. The threshold for intervention, therefore, is set lower than with other hypertensive emergencies (ie, systolic BP exceeding 160 mm Hg). Magnesium sulfate is considered first-line therapy for all cases of preeclampsia and eclampsia. It relaxes smooth muscle (partly through calcium antagonism), which leads to some decrease in peripheral and cerebral vascular resistance, limits cerebral edema formation by protecting the blood-brain barrier, and has central anticonvulsant activity. However, its antihypertensive effects are modest, and additional treatment is typically needed to control BP. Hydralazine and labetalol by IV bolus are equally effective for this purpose and have a limited impact on placental blood flow. Nicardipine is a reasonable alternative and may produce a more profound decrease in BP than labetalol.

Sympathetic Crises

Hyperadrenergic states can result from endogenous sources of catecholamine excess (ie, pheochromocytoma) but, more commonly, they are triggered by the intake of exogenous substances that interfere with norepinephrine—and to a lesser degree, epinephrine—metabolism, such as cocaine, amphetamines, and tyramine-containing foods, especially in patients on monoamine oxidase inhibitors. The net result is a cardiostimulatory and vasopressor response that manifests clinically as tachycardia and marked HTN. In patients with cocaine or amphetamines intoxication, such peripheral effects are compounded by central sympathetic activation, and the hemodynamic derangements can often be improved by the administration of benzodiazepines and other sedative medications.

When BP is persistently elevated and target organ compromise is present, antihypertensive treatment will be needed. Phentolamine, a reversible pure alpha blocker, is considered first-line therapy, producing a reliable decrease in peripheral and coronary vasoconstriction, with few adverse effects. Nitroglycerin can also be used and is specifically indicated for patients with associated
Chest pain and suspected coronary artery vasospasm. Other agents, including fenoldopam, clevidipine, nicardipine, and sodium nitroprusside, are acceptable alternatives. Heart rate control may also be needed, especially in patients with pheochromocytoma, in whom adrenal release of epinephrine may be particularly high, and a short-acting beta blocker such as esmolol is ideal for this purpose. However, to avoid precipitation of unopposed alpha receptor activity and a worsening of HTN, beta blocker therapy should be paired with a vasodilator. Although labetalol has combined alpha and beta blocker properties, beta receptor effects strongly predominate when the drug is administered in IV form (alpha/beta ratio of 1:7). Consequently, IV labetalol is susceptible to a similar differential response and should be used with caution in the setting of catecholamine excess.

**Chronic Antihypertensive Therapy**

Poorly controlled chronic HTN on a single visit or a clear trend toward persistently elevated BP over time requires referral for timely follow-up, with reinforcement of goal BP recommendations and emphasis on the need for lifelong dietary and medication compliance. Initiation of oral antihypertensive therapy for new-onset HTN and re-initiation or uptitration for patients with chronic HTN is appropriate from the ED if follow-up cannot be ensured. However, it is unclear whether this practice will have any impact on long-term outcomes, it is associated with a substantial reduction in BP at follow-up and appears to be safe.

Although there are multiple medication options, a relatively simple algorithm for prescribing chronic antihypertensive therapy has been proposed by the AHA, starting with a thiazide diuretic for most patients. Calcium channel blockers, ACE inhibitors, and angiotensin receptor blockers (ARBs) are included as acceptable first-line alternatives and recommended as add-ons for patients with persistent, poorly controlled BP. Because most patients with stage II HTN will ultimately require multiple agents to control their BP, initiation of two-drug therapy when the systolic BP is higher than 160 mm Hg or diastolic BP higher than 100 mm Hg is recommended. There is increasing evidence that improved compliance with reduced side effects and outcome benefit can be achieved using low-dose combination tablets, especially combined ACE inhibitors and thiazide-like diuretics.

The general approach proposed by the JNC 8 is similar but includes specific recommendations about the use of thiazide diuretics or calcium channel blockers as first-line therapy in blacks and ACE inhibitors or ARBs in patients with chronic kidney disease. However, unlike the JNC 7, preferential use of ACE inhibitors or ARBs in diabetic patients is no longer recommended in JNC 8, and lower BP targets (ie, <130/80 mm Hg) for diabetics and those with chronic kidney disease are no longer endorsed. Moreover, the use of beta blockers as primary therapy has been greatly deemphasized, with inadequate BP control despite other maximum dosed agents, or the presence of underlying coronary artery disease or heart failure, serving as the main indications. Preferential beta blocker use was specifically emphasized in a recent scientific statement on the treatment of HTN in patients with coronary artery disease, as was a lower target BP (<130/80 mm Hg) when myocardial infarction, cerebrovascular disease, peripheral vascular disease, or heart failure is present.

Neither the AHA algorithm nor JNC 8 recommendations specifically address treatment in the ED, but the basic principles of chronic antihypertensive therapy are relatively consistent and there is little reason to deviate from convention. Accordingly, a modified approach to the initiation and escalation of antihypertensive therapy for use in ED patients without significant comorbidity is presented in Fig. 74.4.

As emphasized throughout this chapter, acute BP reduction in the ED provides absolutely no benefit to patients with chronic HTN and exposes them to unnecessary risk of potential hypoperfusion in regions in which blood flow has been governed by long-standing autoregulation. When these patients have symptoms such as headache or chest pain, and there is no suspicion of acute TOD, treatment should be directed toward the symptoms, not the BP. Anxiolytic or analgesic medication administration accompanied by resumption of chronic oral antihypertensive therapy is more rational and beneficial than initiation of short-acting antihypertensive therapy. However, care should be taken to avoid prescribing NSAIDs and other medications that can have a negative impact on BP control and results in the development of cardiovascular complications.

**DISPOSITION**

Individuals without evidence of acute TOD can be discharged home, but hypertensive emergency patients warrant admission, usually to an intensive care unit. Clinical features such as chest pain, dyspnea on exertion, or worsening renal function may confuse the picture, and short-term evaluation in an observation unit can be useful to determine whether the acute presentation represents a true emergency.

Outcomes associated with a given hypertensive emergency are largely a function of underlying TOD. However, data from STAT
have suggested that severe HTN (at least in the subset of patients in whom IV antihypertensives are administered) is a high-risk condition with in-hospital and 30-day mortality rates of 6.9% and 11%, respectively, and a 90-day readmission rate of nearly 40%. When associated with AKI, mortality is even greater, with an odds ratio of 1.05 \((P = .03)\)/10 mL/min estimated GFR decline.\(^{103}\) Although the risk for short-term deterioration is minimal in patients with elevated BP who lack evidence of acute TOD, the long-term risk of cardiovascular, cerebrovascular, and renovascular disease is relatively high,\(^8,102\) underscoring the need for development of effective, patient-centric models of chronic HTN care at the system level.\(^9\)

### KEY CONCEPTS

- Elevated blood pressure with or without associated symptoms is exceedingly common in the ED.
- A true hypertensive emergency is defined by the presence of acute target organ damage and is distinct from other clinical presentations.
- An organ system–based approach to the evaluation and management of patients with elevated blood pressure can optimize decision making while ensuring timely delivery of antihypertensive therapy to those who need it.
- For patients who lack acute TOD, immediate antihypertensive therapy is not needed. However, emergency clinicians can play an important role in the care of this group, providing screening and ongoing surveillance to prevent secondary complications of this disease.
- Administration of a short-acting, potent antihypertensive agent such as clonidine, hydralazine, or nifedipine simply to improve BP values may be harmful and is not recommended in the ED.

CHAPTER 74: QUESTIONS & ANSWERS

74.1. An 85-year-old man presents with acute onset of right-sided weakness that began 1 hour before arrival. His family states that he was recently diagnosed with dementia and has refused to take any of his medications for more than 1 week but had otherwise been relatively healthy. Emergency medical services (EMS) reports a prehospital blood pressure of 240/110 mm Hg. On examination, the patient has clear evidence of an acute stroke with severe deficit (National Institutes of Health [NIH] Stroke Scale = 24), but his gag reflex is intact. His initial blood pressure is 230/110 mm Hg. A head computed tomography (CT) scan shows diffuse white matter ischemic disease but no evidence of acute infarct or hemorrhage. The most appropriate next step is which of the following?

A. Contact neurosurgery for intracranial pressure monitoring.

B. Give a dose of tissue plasminogen activator (tPA) immediately.

C. Give sublingual nifedipine.

D. Intubate and paralyze the patient.

E. Repeat the blood pressure and, if 185/110 mm Hg or higher, start a nifedipine infusion at 5 mg/hr.

Answer: E. Despite his advanced age, this is a relatively high-functioning individual with acute onset of a severe stroke. He is within the time window for administration of tPA, but his blood pressure is excessively elevated. According to the American Heart Association/American Stroke Association guidelines, efforts should be made to reduce his blood pressure to less than 185/110 mm Hg before tPA administration. Other agents, such as labetalol, would also be appropriate to use.

74.2. A 27-year-old woman presents with lower back pain for 1 week. She recently moved into the community and has been busy unpacking and moving furniture. She denies any neurologic symptoms and has no medical history. Her
triage blood pressure is 170/110 mm Hg, but vital signs are otherwise normal. With the exception of appreciable muscle spasm in her lower back, the physical examination is normal. You give her 10 mg of diazepam and observe her for 1 hour. She is feeling better but her blood pressure is still elevated, at 165/90 mm Hg. At this point you should do which of the following?
A. Give her 0.2 mg of clonidine.
B. Ignore the blood pressure and discharge her without follow-up.
C. Order a renal ultrasound scan.
D. Order a 24-hour urine metanephrine and normetanephrine test.
E. Take a more extensive history to see if she is taking oral contraceptives.

Answer: E. This patient’s blood pressure elevation is clearly not a reaction to her pain, and some further questioning is needed to identify a potential cause. In young women, oral contraceptive agents are a treatable cause of hypertension and should be considered when elevated blood pressure is encountered in these patients. Of note, the likelihood of contraceptive-related hypertension increases with the duration of use. It would not be unreasonable to discharge the patient without further exploring the potential cause of her elevated blood pressure, provided some provision of follow-up was sought. The clinical picture is inconsistent with renal artery stenosis or pheochromocytoma, and an evaluation for these conditions would be inappropriate at this point.

74.3. A 50-year-old man complains of dull chest pain that began 4 hours before arrival. The patient states he awoke this morning feeling well and that the pain began while shoveling his driveway. He has a 20-year history of hypertension and diabetes but has always been compliant with his medications, which include metformin, Norvasc, and Diovan. His initial blood pressure is 215/120 mm Hg, and his heart rate is 100 beats/min. On examination, his lungs are clear, heart sounds are normal, pulses are bounding and symmetric, and there are no neurologic deficits. An electrocardiogram shows nonspecific T wave inversions in the lateral leads, with no evidence of ST segment elevation or depression and normal intervals. The serum troponin level is elevated.

Which of the following is the most likely explanation for his clinical presentation?
A. He has a ruptured dissecting aortic aneurysm that is leaking blood into the retroperitoneal space.
B. He is suffering from a massive pulmonary embolism.
C. He strained an intercostal muscle while shoveling.
D. He is suffering from subendocardial ischemia triggered by a cycle of increased afterload that began while he was shoveling.
E. His right coronary artery is 100% occluded.

Answer: D. Increased afterload can be triggered by exertional activation of the sympathetic nervous system. In the presence of long-standing hypertension, ventricular and aortic stiffness are likely to develop, increasing the potential for afterload-mediated effects on the heart. When suddenly faced with increased resistance, the left ventricular pressure may rise, leading to intrinsic compression of subendocardial myocytes and ischemia. Coupled with earlier transmission of the reflected arterial wave form, the diastolic coronary filling time may also be diminished, producing a clinical picture of acute coronary syndrome. He may also have a coronary artery lesion on which this is superimposed but, as described, the likelihood of his clinical presentation being caused by a complete right coronary occlusion is quite low.

74.4. Which of the following funduscopic findings would be the earliest indicator of acute hypertensive retinopathy in a comatose patient whose blood pressure is 260/140 mm Hg?
A. Copper and silver wiring appearance to the retinal arterioles
B. Cotton wool spots
C. Diffuse atrioventricular (AV) nicking
D. Focal intraretinal periarteriolar transudates
E. Retinal hemorrhages

Answer: D. Focal intraretinal periarteriolar transudates are the first abnormality to appear with acute hypertensive retinopathy, preceding all other findings, including cotton wool spots and disk edema. Other findings that are listed may also be seen, but they are indicative of chronic, not acute, retinal involvement. It is important to remember that acute retinal abnormalities may be absent in hypertensive emergency patients and, although funduscopy is an important tool, the diagnosis should be based primarily on the results of the clinical examination.
Aortic Dissection

Felix K. Ankel | Stephen C. Stanfield

PRINCIPLES

Aortic dissection (AD) is a longitudinal cleavage of the aortic media created by a dissecting column of blood. The term dissecting aortic aneurysm has been inaccurately applied to this entity since 1819, when Rene Laennec first used the term aneurysme dissequant. Today, the term aortic dissection is preferred to dissecting aortic aneurysm because the affected aorta is only rarely aneurysmal. In 1955, Dr. Michael DeBakey and his team outlined the principles that remain the basis for the surgical treatment of this entity. Medical treatment of aortic dissection was first advocated in the 1960s and is indicated for certain types of dissections. Another milestone in the management of aortic dissection was the establishment of the International Registry of Acute Aortic Dissection (IRAD) in 1996. The registry is a multinational repository of data that has been collected from 30 international centers of excellence and clinical investigators from 11 countries. Knowledge gained from the registry has been crucial because randomized controlled studies are difficult to conduct in the setting of a condition with such a high mortality. The next major advance in the treatment of AD came in the late 1990s with the implementation and development of endovascular stent graft techniques for the treatment of certain types of aortic dissection. These interventional techniques have since revolutionized the treatment of some types of dissections. Despite advances, in-hospital mortality rate for patients treated for aortic dissection remains at 27%.

Epidemiology

Aortic dissection occurs three times more often in men than women, although women are more likely to present later and have a poorer prognosis. The incidence of aortic dissection also increases with age. The exact incidence and prevalence of aortic dissection are difficult to determine because of underreporting of this condition. Mortality is 1 to 5/100,000 population/year. Hypertension is the most common risk factor associated with this condition. Mortality is 1 to 5/100,000 population/year. Hypertension is the most common risk factor associated with aortic dissection and is seen in most patients. A history of cardiac surgery is present in 18% and bicuspid aortic valve in 14% of all patients with aortic dissections but is found more often in proximal dissections. Atherosclerosis is rarely involved at the site of dissection. Patients with aortic dissection may have a positive family history.

Aortic dissection is uncommon before the age of 40 years, except in association with congenital heart disease, connective tissue disease, or inflammatory vasculitides. As many as 44% of patients with Marfan syndrome, if untreated, develop aortic dissection and account for about 5% of cases. Women with Marfan syndrome are at particular risk during pregnancy. In patients without connective tissue disease and with an aortic root size smaller than 40 mm, pregnancy does not appear to be an independent risk factor. Loeys-Dietz syndrome is an autosomal dominant genetic syndrome associated with aortic aneurysms and skeletal features similar to Marfan syndrome. The vascular disease in these patients is rapidly progressive, and the mean age of death is 26 years. Inflammatory vasculitides associated with thoracic aortic disease include Takayasu arteritis, giant cell arteritis, Behçet disease, and syphilis. Acute aortic dissection also occurs with stimulant use, exertion, cardiac surgery or intraaortic balloon pump insertion.

Blunt trauma from a high-speed deceleration injury usually causes traumatic aortic rupture, which is an entity distinctly different from aortic dissection (see Chapter 38).

Anatomy and Physiology

With each contraction, the heart simultaneously twists and swings from side to side, resulting in flexion of the ascending aorta and descending aorta. The descending aorta flexes just distal to the left subclavian artery, where the mobile aorta is tethered. At an average of 70 heartbeats/min, this sequence occurs about 37 million times annually, causing a repetitive stress on the aorta. The aortic wall has three distinct layers—intima, media, and adventitia. The media is composed of elastic tissue and smooth muscle that give the aorta its properties for distensibility and integrity.

Dissection occurs through a degeneration of the media, characterized by loss of smooth muscle cells and elastic tissue and accompanied by scarring, fibrosis, and hyaline-like changes.

Pathophysiology

Medial degeneration is a precursor to aortic dissection and can be seen with normal aging. Hypertension hastens the progress of medial degeneration. Although initially thought to be noninflammatory, more recent evidence has suggested inflammatory cell infiltration in medial degeneration.

The repetitive hydrodynamic forces produced by the ejection of blood into the aorta with each cardiac cycle contribute to weakening of the aortic intima and to medial degeneration. These hydrodynamic forces primarily affect the ascending aorta. Sustained hypertension intensifies these forces and results in an increase in medial degeneration. A bicuspid valve, occurring in 1% to 2% of the population, is the most common congenital abnormality affecting the aortic valve and proximal aorta. A bicuspid aortic valve may disrupt laminar flow and reorient the flow of blood toward the aortic wall, producing local injury. In Marfan and Ehlers-Danlos syndromes, normal hydrodynamic forces act on an aortic media that is already weakened.

As a result of medial degeneration and repeated flexion of the aorta, hydrodynamic stress tears the aortic intima, and a column of blood gains access into the aortic media. An alternative theory suggests that these forces damage the vasa vasorum of the aorta, which rupture and hemorrhage into the aortic media; this may explain the absence of an intimal tear in some cases of dissection. Regardless of which of these theories is correct, the depth of penetration into the media and distance and direction of dissection are at least partially determined by the degree of medial degeneration.

Once a dissecting hematoma is established in the media, migration of the hematoma occurs in an antegrade or retrograde fashion, or both, forming a so-called false lumen. The false lumen forms in the outer half of the media and propagates until it...
ruptures back into the true lumen of the aorta, resulting in a rare spontaneous cure, or through the adventitia into the pericardial sac or pleural cavity. Because the outer wall of the aorta that contains the hematoma is thin, rupture is much more likely to occur to the outside. The most important factors favoring continued dissection of the aorta are the degree of elevation of blood pressure and the steepness (slope) of the pulse wave (upstroke pattern on apex cardiogram, dP/dt). Both these hemodynamic factors need to be controlled to halt migration of the hematoma.

**Classification**

Anatomic classification is important for diagnosis and therapy. The Stanford Classification is the most commonly used system and is based on the anatomic location of the dissection. Type A dissections involve the ascending aorta and account for approximately 62% of all dissections. Type B dissections involve only the descending aorta and account for 38% of dissections (Fig. 75.1). Dissections that involve the ascending aorta are more often lethal than those limited to the distal aorta and call for a different therapeutic approach. Patients with distal dissections tend to be older, smokers with chronic lung disease, and more often have generalized atherosclerosis and hypertension compared with patients who have proximal aortic dissections. A dissection is acute if it is less than 2 weeks’ duration, subacute between 2 and 6 weeks duration, and chronic if present for longer than 6 weeks.

Two other aortic conditions are closely related to aortic dissection, intramural hemorrhage, and penetrating atherosclerotic ulcer. Both groups of patients have clinical symptoms and management recommendations similar to those for patients with aortic dissection. An intramural hemorrhage is a contained hematoma within the aortic wall and occurs in about 10% of aortic dissections. Rupture of the vasa vasorum is believed to be the initial event. Penetrating atherosclerotic ulcers of the aorta occur in older hypertensive patients with evidence of coronary artery disease. Computed tomography (CT) shows a focal ulceration without dissection, usually in the distal descending aorta. The progression of penetrating ulcers results in progressive aortic enlargement, with saccular and fusiform aneurysm formation. Patients can have an intramural hematoma and penetrating atherosclerotic ulcer.

**CLINICAL FEATURES**

**History**

According to data gathered from the IRAD, pain is the most common presenting complaint, affecting more than 90% of patients. Most cases of painless aortic dissection are chronic in nature. The pain is usually excruciating, occurs abruptly, is most severe at onset, and is typically described as sharp more often than tearing or ripping. A family history of thoracic aortic disease may be reported.

The location of the pain may help localize the dissection. Anterior chest pain is associated with the ascending aorta, neck and jaw pain with the aortic arch, pain in the interscapular area with the descending thoracic aorta, and pain in the lumbar area or abdomen with involvement below the diaphragm. Migration of the pain consistent with propagation of the dissection suggests aortic dissection but occurs in only 17% of cases. The onset of aortic dissection is often accompanied by visceral pain symptoms, such as diaphoresis, nausea, vomiting, lightheadedness, and severe apprehension.

Syncope occurs early in aortic dissection in approximately 9% of cases and may be the sole presentation in some patients. It usually heralds dissection into the pericardium, causing pericardial tamponade, but may occur from transient interruption of blood flow to the cerebral vasculature. Other causes of syncope from aortic dissection are hypovolemia, excessive vagal tone, and cardiac conduction abnormalities. Patients with aortic dissection and syncope have a higher mortality. Neurologic symptoms such as focal weakness or change in mental status occur in up to 17% of cases.

**Physical Examination**

The presentation varies greatly, depending on the patient and location and extent of the dissection. Generally, the patient appears apprehensive. Most patients have a history of chronic hypertension that may be exacerbated by a catecholamine release related to the acute event. Severe hypertension refractory to medical therapy may occur if the dissection involves the renal arteries with subsequent renin release. If hypotension is present, either the dissection has progressed back into the pericardium, with resulting pericardial tamponade, or hypovolemia has occurred from rupture through the adventitia.

Pseudohypotension, a condition in which the blood pressure in the arms is low or unobtainable, and the central arterial pressure is normal or high, may be present. This results from the interruption of blood flow to the subclavian arteries.

Aortic regurgitation occurs in up to 32% of patients and is more common with type A dissection. The murmur of aortic insufficiency may have a musical vibrating quality of variable intensity, and congestive heart failure may develop. The patient with presumed aortic dissection should be examined carefully for findings that suggest hemorrhage into the pericardium or tamponade, such as jugular venous distention, muffled heart sounds, tachycardia, and hypotension.

When the integrity of one of the branches of the aorta is compromised, the expected ischemic findings occur. Pulse deficits and discrepancies in blood pressure between the limbs can be helpful, if present, but have a sensitivity of only around 30%. Usually, these are present in the upper extremities and result from involvement of one or both of the subclavian arteries. Location of one or both common iliac or superficial femoral arteries may produce pulse deficits in the lower extremities. Arterial obstruction may occur by either of two mechanisms. An intimal flap produced by the dissection may cover the true lumen of a branch vessel, or the dissecting hematoma may compress an adjacent true lumen. Frequent reexamination may detect transient pulse deficits. A so-called deadly triad of absence of chest pain, hypotension, and branch vessel involvement is an independent predictor of in-hospital death.

Neurologic findings are related to the site of blood flow interruption. Proximal dissections are a more frequent cause of strokes.

DIAGNOSTIC CONSIDERATIONS

Differential Diagnoses

The differential diagnosis for the patient with symptoms suggestive of aortic dissection is extensive. Signs and symptoms associated with aortic dissection vary and depend on the extent of aortic and branch vessel involvement. Patients with the ultimate diagnosis of aortic dissection are often initially thought to have other conditions, such as myocardial ischemia, congestive heart failure, or pulmonary embolus. Several clinical syndromes are particularly suggestive of aortic dissection—chest pain that is of sudden onset, migratory pain, chest pain with concomitant neurologic deficits or syncope, and chest pain with pulse deficits. Although chest pain is the most common symptom of aortic dissection, it is also the most common presenting complaint of at least three other serious and more common clinical entities—acute MI, pulmonary embolus, and pericarditis. An electrocardiogram (ECG) can be helpful in excluding MI, although aortic dissection and MI may coexist as a result of the dissection proceeding retrograde to the ostium of a coronary artery and causing infarction. In cases in which aortic dissection is excluded, CT may reveal other abnormalities that explain a patient's presentation (eg, pulmonary embolus). Transesophageal echocardiography (TEE) is helpful in identifying causes of chest pain other than aortic dissection (eg, cardiac ischemia).

When the initial presentation of the aortic dissection is pain or dysfunction in an extremity resulting from disruption of the blood supply, peripheral neurologic diagnoses should be included in the differential diagnosis. An aortic dissection may involve the carotid artery and present as a stroke mimic. The diagnosis of aortic dissection should be considered in any patient with a new diagnosis of pericardial effusion, pericardial tamponade, or aortic insufficiency.

Diagnostic Testing

Routine laboratory tests are of little value in the diagnosis of aortic dissection. The hemoglobin level usually is normal or unchanged from the patient’s baseline. The leukocyte count is commonly mildly elevated. Recently, there has been increasing interest in the biochemical diagnosis of acute aortic dissection, including using D-dimer levels. Several authors have suggested that a negative D-dimer makes a diagnosis of aortic dissection unlikely, but currently there is insufficient evidence to support using a D-dimer as a sole screening test for aortic dissection. In addition, the following conditions may result in a low or false-negative D-dimer value in patients with proven aortic dissections: presence of intramural hematomata or thrombosis, short dissection length, and young age of patient. Recent studies have also revealed a negative correlation between the absolute D-dimer values and time from onset of symptoms. As a result, the 2010 guidelines from several major specialty societies, as well as the 2014 Clinical Policy Statement from the American College of Emergency Physicians, have recommended against the practice of using D-dimer to exclude the presence of aortic dissection.

Electrocardiography

The ECG is often useful in excluding MI; however, 15% of patients with aortic dissection may have electrocardiographic abnormalities suggesting ischemia. Proximal dissections that involve the right coronary artery may show an inferior wall MI, and the constellation of symptoms and signs—pain, diaphoresis, hypotension—may be difficult to distinguish from those associated with primary acute MI. The ECG typically shows left ventricular hypertrophy in 26% of cases, reflecting long-standing hypertension. Other findings include nonspecific ST-T wave changes and prior Q wave infarction. No abnormalities are noted on the ECG in 31% of cases (Table 75.1).

Chest Radiography

Routine chest radiographic studies are abnormal in 80 to 90% of patients, but the abnormalities are nonspecific and rarely diagnostic. Mediastinal widening is present in up to 61% of chest radiographs obtained from on patients with chest pain. The widening may occur in any portion of the aorta and may be difficult to differentiate from the aortic tortuosity associated with chronic hypertension. Up to 12% of patients with aortic dissection have a normal chest radiograph (see Table 75.1). A plain chest radiograph is inadequate for ruling out aortic dissection.

Other helpful radiographic signs include a double-density appearance of the aorta, suggesting true and false channels,
localized bulge along a normally smooth aortic contour, disparity in the caliber between the descending and ascending aorta, obliteration of the aortic knob, and displacement of the trachea or nasogastric tube to the right by the dissection. Previous chest roentgenograms, when available, are useful for comparison. Regardless of findings on the chest radiograph, further imaging is necessary in the setting of acute chest pain and concern for aortic dissection.

Echocardiography

Transthoracic echocardiography (TTE) is an insensitive tool for detecting aortic dissection because it does not visualize the aortic arch or much of the descending aorta, and imaging quality may not be optimal because of the patient’s body habitus. While more sensitive imaging tests are being scheduled, however, TTE can provide valuable information about pericardial effusion or aortic regurgitation and can help determine whether cardiac tamponade is the cause of hypotension in a patient with aortic dissection.

TEE is highly sensitive (Table 75.2) for the diagnosis of aortic dissection. The proximity of the esophagus to the aorta and ability to use higher transducer frequencies help visualize the entire aorta and detect pericardial effusion and aortic regurgitation. TEE can be quickly performed at the patient’s bedside with sedation or light anesthesia and does not require radiation or contrast agent injection. Visualization of the distal ascending aorta and proximal arch was formerly difficult because of the interposition of the air-filled trachea and left mainstem bronchus, but evaluation of this so-called blind spot has been aided by biplane and multiplane probes.

The diagnostic accuracy of TEE depends on the experience and availability of the echocardiographer. It is the primary diagnostic method in many institutions for detecting aortic dissection and is the procedure of choice in unstable patients who cannot leave the resuscitation area or the operating room.

Computed Tomography

CT aortography is a reliable test for diagnosing aortic dissection (see Table 75.2) and is the diagnostic test of choice in most institutions. Findings suggestive of aortic dissection include dilation of the aorta, identification of an intimal flap, and clear demonstration of the false and true lumens (Fig. 75.2). Sixty-four-slice (or more) multidetector computed tomography (MDCT) is being used in some centers as part of a triple rule-out CT (TRO CT) protocol for patients with low to moderate risk of acute coronary syndrome in whom pulmonary embolus and aortic dissection are also being considered. However, the larger dose of ionizing radiation, larger volumes of iodinated contrast material, and low incidence of aortic dissection in TRO CT studies limits feasibility of routinely using TRO CT to rule aortic dissection.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is an appealing option for the detection of low-grade aortic dissection in stable patients in whom the diagnosis is uncertain. Sensitivity and specificity are excellent (see Table 75.2). MRI often demonstrates the site of intimal tear, type, and extent of dissection, presence of aortic insufficiency, and differential flow velocities in the true and false lumens in the aortic side branches without contrast material or ionizing radiation and is noninvasive. Its availability, however, is limited and it is difficult to perform in unstable patients. It is particularly useful for the evaluation of chronic aortic dissection, in the follow-up of postoperative patients, and for monitoring nonoperative patients for progression of the dissection.

Choice of Diagnostic Test

Although aortic dissection can be suspected on the basis of the history and physical examination, diagnostic imaging is necessary to establish or rule out the diagnosis. With a mortality rate in excess of 1%/hour after the onset of aortic dissection, a diagnostic study should be performed as soon as feasible. Frequently, more than one test is required to make the diagnosis and assess associated complications.

The clinical strategy should consider the following: (1) technological capabilities available at the institution; (2) institution-specific sensitivities and specificities for the diagnostic tests; (3) benefits of diagnosing alternative causes of chest pain; and (4) ease of performing each test, especially after hours. Some tests (eg, CT, MRI, aortography) may require moving a potentially unstable patient outside the emergency department (ED). In IRAD, the initial choice of diagnostic test was CT in 61%, TEE or TEE in 33%, aortography in 4%, and MRI in 2% of patients. The actual sensitivities of diagnostic tests in IRAD were CT, 93%, TEE, 88%, aortography, 87%, and MRI, 100%, and patients averaged 1.85 imaging studies. A meta-analysis has suggested that TEE, helical CT, and MRI are of similar diagnostic value in ruling aortic dissection in or out.

Unless institutional circumstances do not permit, contrast CT aortography is recommended as the test of first choice. In patients with renal failure or contrast allergy, or those considered too unstable to undergo CT scanning, TEE is recommended. If the patient has a diagnostic (ie, positive) transthoracic echo, the diagnosis is established, but additional confirmatory studies may, or may not be required depending on the preference of the

clinician who will be assuming care of the patient. A negative transthoracic echo does not exclude dissection, and further imaging is always indicated.

**MANAGEMENT**

**Emergency Department**

Early therapy for aortic dissection is critical and should be initiated before confirmation of the diagnosis while diagnostic tests are being performed. Opioids should be administered in adequate doses to control pain and decrease sympathetic tone. Patients with aortic dissections are typically hypertensive. The two goals of medical management are to reduce blood pressure and decrease the rate of rise of the arterial pulse (dP/dt) to diminish shearing forces. A target blood pressure of 100 to 120 mm Hg systolic and a heart rate less than 60 beats/min are recommended. β-Adrenergic blockers are the cornerstone of aortic dissection management and are effective when used as the sole agent, in addition to opioid analgesia for pain. Because vasodilators such as sodium nitroprusside or fenoldopam reflexively increase the heart rate and may also increase the dP/dt, they require concomitant use of a beta blocker. Initial therapy with esmolol or labetalol, as described below, and use of opioid analgesia such as morphine or fentanyl for pain is recommended.

**Recommended Therapy**

Esmolol and labetalol are titratable, short-acting beta blockers that can be used in treatment for hemodynamic control in aortic dissection. Esmolol is an ultra–short-acting beta blocker given as an initial bolus of 500 μg/kg, followed by an infusion of 50 to 200 μg/kg/min. Although esmolol is often used in the management of aortic dissection, an additional agent is typically required to augment the antihypertensive effects. Labetalol has both alpha and beta blocking activity and is given as an initial series of 20-mg IV boluses every 5 to 10 minutes, incrementally increased to 80 mg IV until a target heart rate of 60 beats/min is reached or a total of 300 mg is given. A maintenance infusion of labetalol is then given at a rate of 1 to 2 μg/min. If a patient is normotensive, a beta blocker should still be used to lower the dP/dt and maintain a heart rate of 60 beats/min. In patients with a history of chronic obstructive pulmonary disease or who are at risk for bronchoconstriction, a selective beta blocker such as metoprolol or atenolol should be considered.

**Alternative Agents**

Sodium nitroprusside was widely used before esmolol and labetalol became available and is a reasonable agent to use, but necessitates concomitant use of a beta blocker to mitigate reflex tachycardia and is comparatively labor intensive to prepare and administer. The initial infusion is 0.5 to 3 μg/kg/min; the infusion is adjusted to reach the same hemodynamic goals described above.

Intravenous (IV) nitroglycerin is often used initially in patients with hypertensive chest pain and possible or uncertain aortic dissection. Nitroglycerin is a less effective arterial dilator than nitroprusside and is less desirable than nitroprusside for the treatment of patients with aortic dissection. Like nitroprusside, nitroglycerin should be accompanied by a beta blocker. A reasonable alternative to nitroprusside may be fenoldopam, although it too has been shown to cause reflex tachycardia and has not been specifically studied in patients with aortic dissection.

Nicardipine can be used as a second-line agent in situations in which beta blockers are not well tolerated. It is a vasoselective calcium channel blocker that belongs to the dihydropyridine class. Nicardipine produces its antihypertensive effect by decreasing peripheral vascular resistance, and it has no negative inotropic effect. In addition, when compared to nitrates, nicardipine has very little effect on heart rate. Although recent studies comparing nicardipine to other agents have been promising, it is still not used as a first-line therapy.

Patients presenting with hypotension secondary to aortic rupture or pericardial tamponade should be resuscitated with IV fluids and expeditiously transported to the operating room if they are to have a chance to survive. Blood pressure should be measured in all four limbs, if necessary, to ensure that this is not a pseudo-hypotension caused by an intimal flap obstructing the extremity in which the blood pressure is measured. In patients with marked hypotension, pericardiocentesis may raise the blood pressure while awaiting definitive surgery.

**Operative and Interventional Repair**

Type A acute aortic dissections require prompt surgical treatment. The aortic segment containing the original intimal tear is resected when possible, with graft replacement of the ascending aorta to redirect blood into the true lumen. If aortic insufficiency is present, it can be corrected through aortic valve resuspension or replacement. Patients with type A dissections have an in-hospital mortality rate of 27% when treated surgically versus an in-hospital mortality of 56% when treated medically.11,21,22

Definitive treatment of type B acute aortic dissections is less clear. These patients, in general, tend to be worse surgical risks. Type B dissections are categorized into two groups based on associated symptoms—complicated and uncomplicated. Complicated dissection is any dissection that has end-organ ischemia, leaking or rupture, aortic dilation, or intractable pain and occurs in 30% of patients with acute type B dissections. Stable asymptomatic patients are categorized as uncomplicated.

Complicated distal dissections are traditionally treated surgically although, in the past decade, this practice has been challenged. Thoracic endovascular aneurysm repair (TEVAR) techniques have been replacing surgery for complicated type B dissections in many centers, especially for patients with renal and mesenteric ischemia.34 Recent studies have reported that mortality rates for patients treated surgically and those treated with stent graft placement have similar initial mortality rates, whereas long-term outcomes favor the interventional approach (Fig. 75.3).

Although evidence supporting widespread use of endovascular intervention has appeared promising, the decision to implement medical therapy alone or in combination with intravascular intervention is complicated and involves complete knowledge of each patient’s particular situation. The decision regarding which treatment modality is beneficial for a particular case should rest with the primary treating physician, and the patient and decision should involve a discussion of the potential risks and benefits of each approach.

**DISPOSITION**

Patients with type A aortic dissection require emergent cardiovascular surgery consultation as well as ED management of blood pressure and heart rate prior to intraoperative repair. Inpatient admission is frequently required to maintain adequate control of blood pressure and heart rate parameters. Patients who present with chronic aortic dissection have already survived their period of greatest mortality risk and are usually treated by blood pressure control and close monitoring, unless complications mandate surgery. Regardless of the type of definitive therapy, all patients who have sustained and survived an aortic dissection require careful long-term treatment. Major complications that may occur with time are rediscussion, development of a localized aneurysm, and progressive aortic insufficiency.

KEY CONCEPTS

- Most patients with aortic dissection have chest pain, typically of sudden onset, sharp, and migratory. Chest pain associated with neurologic symptoms or syncope should increase the likelihood of aortic disease.
- Physical examination findings may include pulse deficit, aortic insufficiency murmur, and neurologic findings, but often the physical examination is not diagnostic, and imaging is essential to establish or exclude the diagnosis of dissection.
- Of the confirmatory tests, CT aortography is recommended. Transesophageal echocardiography is also an excellent test and can be used when CT is not available or for patients with contrast allergy, renal insufficiency, or critical illness that precludes CT scanning.
- Patients with type A aortic dissection require emergent cardiovascular surgery consultation as well as ED management of blood pressure and heart rate prior to intraoperative repair.
- Patients with acute type B dissections also require stabilization of the blood pressure and pulse to prevent progression of symptoms and frequently require admission as inpatients for further monitoring. Long-term treatment decisions of type B dissections should be based on the patient’s current symptoms, input from the cardiovascular surgical team, and discussion with the patient regarding risks and benefits of therapy.

CHAPTER 75: QUESTIONS & ANSWERS

75.1. Which valvular abnormality is associated with aortic dissection?

A. Aortic regurgitation
B. Aortic stenosis
C. Mitral regurgitation
D. Mitral stenosis

Answer: A. Aortic regurgitation occurs in up to 32% of patients and is more common with type A dissections. A bicuspid aortic valve is found in 14% of patients with dissections and may predispose to dissection by disrupting the blood flow.

75.2. A 67-year-old man presents with ripping substernal chest pain. Physical examination is remarkable for blood pressure, 180/110 mm Hg, pulse, 116 beats/ min, respiratory rate, 18 breaths/min, and temperature, 37.2°C (98.9°F). The electrocardiogram (ECG) is unremarkable. Which of the following diagnostic studies is the best test to rule out aortic dissection?

A. Chest radiograph
B. Computed tomography (CT) aortography
C. Magnetic resonance imaging (MRI)
D. Transesophageal echocardiography

Answer: B. CT aortography is a reliable test with the best combination of high sensitivity and specificity for diagnosing aortic dissection. A chest radiograph may be a fast screening test, but 12% will be falsely normal. MRI is more sensitive but is not always available and is unsuitable for unstable patients.

75.3. A 59-year-old man presents with sharp chest pain. Physical examination is remarkable for blood pressure 192/116 mm Hg, pulse, 116 beats/ min, respiratory rate, 16 breaths/min, temperature, 37.2°C (98.9°F). Chest auscultation reveals a diastolic murmur. Which of the following medications is the best initial treatment choice for his condition?

A. Dobutamine
B. Esmolol
C. Nifedipine
D. Phentolamine

Answer: B. Esmolol and labetalol are titratable, short-acting beta blockers that can be used as monotherapy for hemodynamic control in aortic dissection. These can be started quickly to control blood pressure but, more importantly, to decrease the rate of pressure change.

75.4. Which of the following is the most common sign or symptom of a patient with aortic dissection?

A. Aortic insufficiency murmur
B. Chest pain
C. Pulse deficit
D. Syncope

Answer: B. Pain is the most common presenting complaint, affecting more than 90% of patients. Syncope, a pulse deficit, and aortic insufficiency murmur are all important to elicit and affect the outcome.
Abdominal Aortic Aneurysm

Christopher B. Colwell | Charles J. Fox

PRINCIPLES

An abdominal aortic aneurysm (AAA) is a true aneurysm, meaning a localized dilation of the aorta involving all three layers (intima, media, and adventitia) of the arterial wall (Fig. 76.1). A false aneurysm, or pseudoaneurysm, is a collection of flowing blood that communicates with the arterial lumen but is not enclosed by the normal vessel wall; it is contained only by the adventitia or surrounding soft tissue. Pseudoaneurysms can arise from a defect in the arterial wall or a leaking anastomosis after AAA repair.

AAA is distinct from aortic dissection, which is sometimes incorrectly referred to as a dissecting aortic aneurysm. In aortic dissection, blood enters the media of the aorta and splits (dissects) the layers of the aortic wall (see Chapter 85). Aortic aneurysm and aortic dissection are distinctly different disease processes, with different clinical presentations, complications, diagnostic methods, and treatments.

An aneurysm can develop in any segment of the aorta, but most are infrarenal. The diameter of the normal adult infrarenal aorta is approximately 2 cm, and a diameter of 3 cm or more defines an AAA.

Epidemiology

AAA is a disease of aging, with prevalence increasing with advancing age and is found in 2% to 5% of men older than 50. The average age at the time of diagnosis is between 65 and 70 years old, with males affected much more often than females. The patient often has concomitant atherosclerotic occlusive disease, including coronary, carotid, or peripheral vessels, which may influence the clinical presentations, complications, diagnostic methods, and management.

Several risk factors for the development of an AAA have been established, but risk factors are epidemiologic, not individual characteristics. An AAA can be found in 5% to 10% of all elderly men who are screened with ultrasonography with increasing prevalence in those who have concomitant coronary artery disease or peripheral vascular disease.1 The presence or absence of risk factors should not strongly influence diagnostic considerations in any individual patient (Table 76.1). A family history of an AAA is a very strong risk factor; those with an affected first-degree relative have a markedly increased risk of developing an AAA. Although awareness of high-risk groups can speed the recognition of AAA, the consideration of AAA should not be restricted to patients in these groups. Recent evidence suggest that women may experience delays in diagnosis and worse operative mortality after ruptured AAA and that up to half of AAAs in the United States occur in women, nonsmokers, or those younger than 65.2

Pathophysiology

AAAs have traditionally been attributed to atherosclerosis, but patients with advanced atherosclerosis have occlusive disease, not aneurysms. Patients with AAA have biochemical abnormalities leading to the loss of elastin and collagen, which are the major structural components of the aortic wall. The propensity to form aneurysms may have a genetic basis, but the exact mode of inheritance is uncertain. The Society for Vascular Surgery recommends labeling the typical degenerative AAA as “nonspecific,” rather than “atherosclerotic,” to reflect this uncertainty surrounding the etiology.

AAAs may also have specific etiologies, such as infection, trauma, connective tissue diseases, and arteritis. However, such aneurysms are rare compared with nonspecific, degenerative aneurysms.

Natural History

AAAs progressively enlarge, ultimately resulting in rupture of the aneurysm and fatal hemorrhage. Although other complications are possible, by far the most common and most clinically significant is rupture.

The most important factor determining the risk of rupture is the size of the aneurysm. The risk of rupture increases dramatically with increased aneurysm size, and most ruptured AAAs have diameters greater than 5 cm. The growth rate of the AAA, in addition to other anatomic factors, may also be important in determining the risk of rupture. Although rupture of aneurysms smaller than 4 cm is rare, an aneurysm is completely “safe.” Any aneurysm can rupture and cause significant consequences.

AAA most commonly ruptures into the retroperitoneum, where hemorrhage may be temporarily limited by clotting and tamponade at the rupture site, but 10% to 30% involve free intraperitoneal rupture, which is often rapidly fatal. Occasionally, rupture occurs into the gastrointestinal tract or the inferior vena cava.

Complications can also arise from an intact AAA. The walls of an AAA are often lined with clot and atheromatous material, which can embolize and occlude distal vessels. Sequelae of occlusion and embolization may be the only diagnostic clues to AAA. Aortic thrombosis may occur rarely and patients can also have complications caused by impingement of the aneurysm on adjacent structures.

In approximately 5% of AAAs, a dense inflammatory and fibrotic reaction develops in the aneurysm wall and adjacent retroperitoneal tissue. In these “inflammatory” AAAs, the periaortic fibrosis may incorporate and obstruct adjacent structures, such as the ureters or duodenum.

The principal concern in the patient with an AAA is the potential for rupture of the aneurysm, which can be prevented only by timely repair.

CLINICAL FEATURES

Unruptured Aneurysms

Because most AAAs do not cause symptoms until they expand or rupture, the prevalence of symptoms in patients with unruptured AAAs is difficult to determine. Patients may have symptoms that lead to the aneurysm’s discovery prior to rupture. These symptoms can include pain in the abdomen, back, or flank; an awareness of
an abdominal mass or fullness; or a sensation of abdominal pulsations.

The pain associated with stable, intact aneurysms often has a gradual onset and a vague, dull quality. It is usually constant but may be described as throbbing or colicky. Acute or severe pain is an ominous symptom that suggests imminent or actual aortic rupture.

In most cases, an AAA is asymptomatic and is discovered incidentally on physical examination, on a radiologic study done for unrelated issues, or by an ultrasonography aneurysm screening program. Symptoms usually do not develop until the aneurysm ruptures.

The most prominent physical finding is a pulsatile, expansile abdominal mass above the level of the aortic bifurcation. If the iliac arteries are also aneurysmal, the mass may extend below the umbilicus. The right border of an AAA may be palpable to the right of midline, whereas a normal or tortuous aorta is usually not. Most intact AAAs are nontender; tenderness suggests aneurysm expansion or rupture.

Symptomatic aneurysms are usually fairly large and are often palpable with a careful abdominal examination. Likewise, the patient with an aneurysm large enough to warrant elective repair often has a palpable abdominal mass. However, an AAA may be difficult to palpate if the aneurysm is small or the patient is obese. Published reports indicate that 30% to 60% of unruptured aneurysms measuring 3.0 to 3.9 cm on ultrasonography can be detected by abdominal palpation; 50% to 70% of aneurysms measuring 4.0 to 4.9 cm and 75% to 85% of aneurysms 5 cm or larger can be palpated. These reports are based on the examination of patients with intact, asymptomatic aneurysms, with the examination specifically directed at sizing the aorta. The sensitivity is likely much lower when the abdomen is not palpated deeply, in hypotensive patients, or those with significant abdominal guarding. There is virtually no risk of causing aneurysm rupture by abdominal palpation.

Physical examination may reveal findings consistent with an AAA even when the aorta is of normal size. A tortuous aorta may feel enlarged, and prominent aortic pulsations, especially in a thin patient, may simulate an aneurysm. Pulsations from a normal aorta may be transmitted to an adjacent abdominal mass. Clinical suspicion of AAA, which includes both the patient’s history and physical examination findings, warrants further investigation.

An abdominal bruit is an uncommon finding in patients with AAAs. The presence of a bruit is also nonspecific, because bruits can originate from a stenotic renal, iliac, or mesenteric artery. A loud continuous bruit suggests the diagnosis of arteriovenous fistula, a rare complication of AAAs.

Perfusion distal to an AAA is usually well maintained, and most patients have normal femoral pulses. Diminished femoral pulses may result from iliofemoral occlusive disease or from hypotension related to hemorrhagic shock in the patient bleeding from a ruptured aneurysm.

Thromboembolic complications can occur spontaneously or when atheromatous plaques are disrupted during invasive intra-vascular procedures. Large emboli can acutely occlude major vessels, such as the iliac, femoral, or popliteal artery, causing painful lower extremity ischemia with absent distal pulses. Rarely, the aneurysm itself can thrombose, rendering both lower extremities acutely ischemic. More commonly, microemboli consisting of cholesterol crystals or clot obstruct small distal vessels, such as the digital arteries of the toes and arterioles and capillaries of the skin. These patients can present with livedo reticularis; one or more cool, painful, cyanotic toes; and palpable pedal pulses. This constellation of findings, often called the blue toe syndrome, is highly suggestive of a proximal source of emboli. When an AAA is the source, the aneurysm is often too small to palpate and only recognized with radiologic investigation.

In rare instances an intact AAA can cause symptoms by compressing adjacent structures, with symptoms representing those structures involved. Large, long-standing aneurysms can cause vertebral body erosion and severe back pain. Compression of the duodenum between the superior mesenteric artery and an AAA can cause duodenal obstruction, vomiting, and weight loss. Obstruction of the ureters in the patient with an inflammatory aneurysm can cause symptoms suggestive of ureteral colic.

### Ruptured Aneurysms

#### Pain-Hypotension-Mass Triad

Although the classic description of a ruptured AAA is the triad of pain, hypotension, and a pulsatile abdominal mass, many patients have only one or two components of this triad, and an occasionally none of these classic features.

Acute rupture is often the first presentation of an AAA. Not infrequently though, patients may have a previously diagnosed AAA where the decision not to operate electively may have been made because the aneurysm was small or the patient was considered too high risk. Any new or acute symptoms in these patients should be considered acute aneurysmal rupture.

Most patients with a ruptured AAA experience pain in the abdomen, back, or flank. The pain is classically acute, severe, and constant and although difficult to locate, can radiate to the chest, thigh, inguinal area, or scrotum. A history of pain may be more difficult to illicit if the patient’s mental status is compromised by severe hypotension.

The source of the pain associated with aneurysm rupture is not clearly understood. It may be caused by expansion of the aortic wall or by stimulation of visceral sensory nerves in the retroperitoneum. Identical pain can occur with intact but acutely expanding aneurysms, which may be impossible to differentiate clinically from ruptured aneurysms.

In patients with a ruptured aneurysm, the duration of symptoms before presentation can vary dramatically. Some patients present immediately after rupture because pain is severe, sudden, in onset, and may be accompanied by hypotension. In others, rupture is initially contained in the retroperitoneum, blood loss is small, pain may be minor, waxing and waning, and the presentation delayed. Rare patients with a ruptured AAA may have symptoms for several days or even weeks before seeking medical attention; therefore a long duration of symptoms does not exclude the diagnosis of ruptured AAA.

Rupture of an AAA may be accompanied by nausea and vomiting in addition to pain or, rarely absent significant pain, and sudden hemorrhage may present as syncope or near-syncope. Compensatory hemodynamic mechanisms may restore blood pressure and cerebral perfusion to normal. Transient improvement in symptoms is common but will be followed by hemodynamic deterioration if the diagnosis and treatment are delayed. Ruptured AAAs are often large, and non-obese patients will have a palpable abdominal mass. The examination may be difficult if abdominal guarding is present or if an ileus causes significant distention; and aortic pulsations may not be prominent if the blood pressure is low.

Hypotension is the least consistent part of the triad, occurring in approximately half of patients, and is often a late finding. When the initial blood loss is small, vital signs may be normal. Patients with initially normal vital signs are more likely to be misdiagnosed and may quickly and unpredictably deteriorate and become hypotensive.

Occasionally, rupture into the retroperitoneum is sealed and contained for many weeks or months. When this occurs, patients develop abdominal or back pain, presumably at the time of aneurysm leakage, which subsequently diminishes or resolves completely. If the diagnosis is made, chronic rupture (organized hematoma) is found at surgery. These patients can have chronic pain and may progress to free rupture and massive hemorrhage at any time.

Aortoenteric Fistula

A primary aortoenteric fistula (AEF) is formed when an unrepaired AAA erodes into the gastrointestinal tract, most commonly in the third or fourth portion of the duodenum. A secondary AEF, a communication between the site of previous aortic surgery and the gastrointestinal tract, can occur as a late complication of AAA repair and should be considered in any patient with a severe gastrointestinal bleed and a history of aortic graft placement. An AAA can rupture into the gastrointestinal tract (AEF) or inferior vena cava (aorto caval fistula).

Early in the formation of a primary AEF, the adjacent AAA erodes through the bowel wall from the outside. This can lead to the leakage of intestinal contents, with local infection and abscess formation. Eventually, breakdown of the aortic wall leads to an AEF and may lead to gastrointestinal bleeding. A patient with an AEF may have abdominal or back pain, fever and other signs of intra-abdominal infection, or gastrointestinal bleeding. Because most of these fistulae are into the duodenum, hemorrhage usually manifests as hematemesis or melena. The initial bleeding results from erosion of vessels in the bowel wall and is often occult or minor. Massive bleeding from rupture into the intestinal lumen can occur days or even weeks after the initial bleeding. Primary AEF, although rare, should be considered in any patient older than 50 years with unexplained severe gastrointestinal bleeding. An AAA diagnosed by history, physical examination, or other modality, presenting with gastrointestinal bleeding should raise the concern for AEF.

Arteriovenous (Aortocaval) Fistula

An arteriovenous (usually aortocaval) fistula arises when periaortic inflammation causes adherence of the aorta to an adjacent vein, with pressure on the vessel walls causing the development of an arteriovenous communication. If concomitant extravasation of blood into the retroperitoneum occurs, the clinical presentation is similar to that of other patients with ruptured AAAs. More commonly, however, the aneurysm ruptures into the vena cava without leaking externally, and the signs and symptoms of a large arteriovenous fistula dominate the clinical picture.

As in other patients with AAAs, a patient with an arteriovenous fistula may have abdominal or back pain. An aneurysm that becomes fistulous with the vena cava is usually large, and 80% to 90% are palpable. A continuous abdominal bruit can be auscultated in approximately 75% of patients with arteriovenous fistulae, and 25% of patients have a palpable abdominal thrill.

Shunting of blood from the arterial to the venous system increases venous pressure, venous volume, and venous return to the heart. Signs and symptoms of high-output congestive heart failure (dyspnea, jugular venous distention, pulmonary edema) are often present. The increased venous volume and pressure can cause lower extremity edema or cyanosis, and dilated superficial veins can be seen on the legs or abdominal wall. Distention and rupture of veins in the bladder mucosa can cause gross or microscopic hematuria, and rectal bleeding can occur for similar reasons. Because of shunting of arterial blood into the venous system, the lower extremities may be cool with diminished pulses.

The patient with an arteriovenous fistula often has renal insufficiency caused by a decrease in renal perfusion as a result of high-output congestive heart failure and increased renal venous pressure. Such patients may exhibit hematuria, which is common when an arteriovenous fistula is present but not in other patients with AAAs. Computed tomography (CT), and preferably computed tomography angiography (CTA), can be useful in diagnosing or ruling out arteriovenous fistula formation.

Differential diagnoses

Symptoms consistent with ruptured AAA; abdominal, back, or flank pain, with or without hypotension, are seen in other diagnosis as well, which can lead to delayed or missed diagnoses (Box 76.1). The most common misdiagnosis is renal colic, followed by

Box 76.1

Common Misdiagnoses in Patients With Ruptured Abdominal Aortic Aneurysms

| Renal colic |
| Acute abdomen |
| Pancreatitis |
| Intestinal ischemia |
| Diverticulitis |
| Cholecystitis |
| Appendicitis |
| Perforated viscus |
| Bowel obstruction |
| Musculoskeletal back pain |
| Acute myocardial infarction |
pancreatitis, intestinal ischemia, other nonspecific intra-abdominal disorders and musculoskeletal back pain. Presentation of epigastric pain and hypotension may lead to a presumptive diagnosis of acute myocardial infarction because patients with a ruptured AAA often have concomitant coronary artery disease, and blood loss from a ruptured aneurysm may diminish coronary perfusion and cause chest pain or electrocardiographic changes consistent with cardiac ischemia. In the setting of abdominal or back pain, these findings do not exclude the presence of a ruptured AAA.

Ruptured AAA should be considered in middle-aged or elderly patients with any part of the classic triad pain, hypotension, and a pulsatile abdominal mass. The diagnosis of ruptured AAA should also be considered in making the diagnoses listed in Box 76.1, especially when the diagnosis is not clear-cut or the patient is at risk for an AAA.

**DIAGNOSTIC TESTING**

**Abdominal Radiography**

Plain film radiography is not indicated in the evaluation of a patient for suspected AAA. A normal plain abdominal radiograph does not exclude the presence of an AAA and rarely identifies alternative pathology. Even if an aneurysm is identified on plain film because it is calcified, imaging with CT is necessary to identify whether the aneurysm is an incidental or culprit lesion in the patient’s presentation (Fig. 76.2).

**Ultrasonography**

Ultrasonography is virtually 100% sensitive in detecting AAAs (Fig. 76.3) when a technically adequate study can be obtained. Measurements of aortic diameter are very accurate and reproducible. Because it is relatively inexpensive and requires no contrast agents or radiation exposure, ultrasonography is also used for aneurysm screening and to follow patients with known aneurysms after they have been characterized with CTA.

Point of care ultrasonography has distinct advantages in the emergency evaluation of a patient with a suspected ruptured AAA. It can be performed very rapidly at the patient’s bedside, obviating the need to take a potentially unstable patient to the radiology suite. If an aorta with a normal diameter throughout its abdominal course is visualized, the patient does not have an AAA. In addition, ultrasonography sometimes provides alternative explanations for the patient’s pain by revealing other conditions, such as acute cholecystitis. Emergency clinicians can accurately identify the etiology of acute nontraumatic abdominal pain, including AAAs using bedside ultrasound.

Point of care ultrasonography does have certain limitations, including being more operator dependent when compared to other modalities, and is therefore more prone to technical or interpretive error. Even more than with elective studies, in the emergency department (ED) the aorta may not be well visualized because of obesity or excess bowel gas. Although ultrasonography is extremely sensitive in detecting an AAA, it cannot be relied on to reveal whether an AAA has ruptured.
Free intraperitoneal or retroperitoneal blood, seen in the presence of an AAA, confirms a rupture. However, the sensitivity of point of care ultrasonography in detecting extraluminal blood is very low. The purpose of the study is to confirm or exclude the presence of an aneurysm; clinical information (or a CT scan) must be used to determine the likelihood of rupture. Ultrasonography with the use of contrast agents may aid in the detection of leaking blood, but the clinical usefulness of this modality has still not been determined. If ultrasonography reveals an AAA in an unstable patient, aneurysm rupture should be presumed, and emergent surgical evaluation for consideration of aneurysm repair should be initiated.

**Computed Tomography**

The abdominal CT scan is the diagnostic test of choice in the evaluation of the stable patient with suspected ruptured AAA and is virtually 100% accurate in determining the presence or absence of an AAA and the presence of bleeding. CT also provides detailed anatomic information about the aneurysm.

An intravenous contrast agent is desirable, but not essential, in emergency situations. With significant, prolonged hypotension or known renal disease, intravenous contrast can be avoided to prevent contrast-exacerbated nephropathy. Intravenous contrast will opacify the aortic lumen and distinguishes the patent lumen from mural thrombus. It can also demonstrate peri-aortic fibrosis, because the soft tissue surrounding an inflammatory AAA will often enhance. Although intravenous contrast is not necessary to identify the aneurysm or acute hemorrhage, contrast will be crucial to accurate sizing and planning if an endovascular approach is being considered.

CT is much more sensitive than ultrasonography in detecting retroperitoneal hemorrhage associated with aneurysm rupture. The reported sensitivity approaches 100% with the use of current-generation scanning technology, with falsely negative studies sometimes occurring with very small ruptures. Blood is seen as a retroperitoneal fluid collection adjacent to the aneurysm, often tracking into the perinephric space or along the psoas muscle (Fig. 76.4).

Although a CT scan sometimes reveals signs of impending aneurysm rupture, it cannot reliably determine whether an AAA is the cause of the patient’s pain or whether rupture of the aneurysm is imminent. An alternative cause of pain can be diagnosed only if the CT scan shows no aneurysm or shows an intact aneurysm and clearly demonstrates an alternative explanation for the patient’s symptoms.

**Other Diagnostic Modalities**

Conventional angiography has no place in the emergency evaluation of the suspected ruptured AAA. Because contrast opacifies only the patent lumen and not mural thrombus, angiography often underestimates aneurysm size and can miss an aneurysm entirely. In addition, angiography is time-consuming and performed away from the ED. If detailed information is needed about the anatomy of the aneurysm or its relationship to nearby vessels, a CT angiogram can provide the needed information.

Magnetic resonance imaging and magnetic resonance angiography are very time-consuming, logistically challenging, and provide no benefit over CT scan. Magnetic resonance scanning is not indicated in the evaluation of a patient with suspected AAA in the ED.

**MANAGEMENT**

**Ruptured Aneurysms**

The patient with a ruptured AAA is unstable until the aorta is cross-clamped in the operating room or stabilized with endovascular techniques. No patient with a known or suspected aortic rupture should be considered stable, regardless of the vital signs or initial hemoglobin level. Ruptured AAA is a time dependent disease, and patients taken to the operating room soon after ED arrival have a significantly higher survival rate than those in whom surgical care is delayed.

When the patient arrives in the ED, large-bore redundant intravenous access should be established and blood sent for type and crossmatch. At least 6 units of blood should be made available initially, with notification to the blood bank of the potential need for massive transfusion. The surgical and anesthesia team should be notified emergently. Further management depends on the hemodynamic status and level of diagnostic certainty.

The hemodynamically unstable patient in whom a ruptured AAA has been diagnosed or is strongly suspected should be taken to the operating room as soon as possible (in this chapter, the term “operating room” includes other locations that may be used for endovascular aneurysm repair) and diagnostic testing should be kept to a minimum. The diagnosis can often be made on clinical grounds and point of care ultrasonography can quickly confirm or exclude the presence of an aneurysm. A thin sliced CT scan of the abdomen and pelvis with intravenous contrast is appropriate only if it can be obtained quickly without compromising the patient’s care. Time-consuming tests can lead to avoidable delay of definitive therapy and increase the risk of exsanguination.

Hypotensive patients may have to be taken to the operating room based on a strong clinical presumption of the diagnosis, without definitive diagnostic imaging. Some of these patients will not have ruptured aneurysms, but they usually have other acute abdominal conditions requiring laparotomy.

Attempts to resuscitate these patients to the point of normalization of vital signs in the ED can waste valuable time and should be avoided. Hypotensive patients need to be taken to the operating room so that the aorta can be clamped, or occluded with a balloon, and hemorrhage stopped.

**Fluid Resuscitation**

The right amount of preoperative volume resuscitation remains controversial. Preoperative hypotension is the strongest predictor of mortality in the patient with a ruptured AAA, although...
correction of hypotension before the aorta is clamped may not improve mortality and may even be harmful as hypotension slows bleeding in patients with AAA and allows local clot formation and tamponade of the rupture site. Raising the intravascular volume and blood pressure before occluding the aorta may dislodge clots and cause further bleeding. Large volumes of crystalloid solution may contribute to bleeding by worsening acidosis and causing a dilutional coagulopathy. These concerns are similar to those in penetrating trauma patients with uncontrolled hemorrhage.

However, delaying resuscitation of hypotensive patients until they reach the operating room may also have deleterious effects. The patient with a ruptured AAA often survives the surgery but dies in the early postoperative period. These deaths are caused by complications of prolonged hypotension, such as myocardial infarction, respiratory failure, and renal failure. The patient with a ruptured AAA is usually elderly, often has coexisting conditions, and tolerates hypovolemia and hypotension poorly.

No prospective studies have compared different preoperative fluid regimens in hypotensive patients with ruptured AAAs, and the optimal resuscitation strategy has not been determined. The priority in these patients is expeditious transportation to the operating room for definitive control of aortic hemorrhage. In the optimal resuscitation strategy has not been determined. The fluid regimens in hypotensive patients with ruptured AAAs, and an a ruptured AAA is usually elderly, often has coexisting conditions, and renal function, patients who are taken for emergency surgery and found to have intact, symptomatic aneurysms have a mortality rate that is anatomically suitable for endovascular repair. The method of repair will depend on the preference and skill set of the surgeon, as well as institutional capability and suitability for an endovascular approach. Planning for the care of such patients should include the development of a well understood protocol or pathway that advises the ED staff about which services to mobilize and which diagnostic tests to perform in patients with suspected ruptured AAA.

Surgery and Mortality
Ruptured AAA is uniformly fatal unless treated surgically. Thus once this diagnosis has been made, repair should be attempted in almost all patients. Attempts have been made to identify patients with a very low likelihood of survival, and it has been suggested that surgery can be withheld in patients with prehospital or ED cardiac arrest. However, there are no variables that can be assessed in the ED, including cardiac arrest, that are universally predictive of a fatal outcome. Repair is indicated unless the patient has comorbidity making surgery unreasonable has a living will or healthcare proxy declining surgery or if the patient is mentally capable and declines surgery. Preoperative hypotension is the most significant predictor of poor outcome in patients undergoing surgery. Although patients with ruptured AAAs have a mortality of 30% to 40% with open repair, endovascular repair of ruptured aneurysms is becoming increasingly more common, even in unstable patients. There is evidence that high volume centers experienced with endovascular repair have a significantly lower operative morbidity and mortality rate.

Not all patients with ruptured aneurysms will have an aorta that is anatomically suitable for endovascular repair. The method of repair will depend on the preference and skill set of the surgeon, as well as institutional capability and suitability for an endovascular approach. Planning for the care of such patients should include the development of a well understood protocol or pathway that advises the ED staff about which services to mobilize and which diagnostic tests to perform in patients with suspected ruptured AAA.

Intact, Asymptomatic Aneurysms
An incidental diagnosis of AAA may be made in the ED. The decision to repair an asymptomatic aneurysm depends on the risk of aneurysm rupture, comorbidities, and surgical risk. Surgical risk is determined by the patient’s age and comorbidities, whereas the risk of rupture is largely a function of aneurysm size.

In two clinical trials, one of which has long-term follow-up, patients with small (<5.5 cm) aneurysms were randomized to early surgery or close follow-up. In the latter group, aneurysms were followed with serial ultrasounds or CT scans, and surgery was performed only if any symptoms developed, rapid expansion was documented, or a diameter of 5.5 cm was reached. Both studies showed equivalent survival rates in the two groups. As a result, fewer small aneurysms are now repaired electively, potentially leaving a larger group of patients who may come to the ED with complications of an AAA.

Traditional Repair
The conventional technique for repair of AAAs is an open approach with a laparotomy. The aneurysm is opened longitudinally and repaired from within (Fig. 76.5). A graft is inserted inside the aneurysm and anastomosed to uninvolved vessels above and below once lumbar vessels are ligated and the mural thrombus evacuated. When possible, a straight graft is used between the infrarenal and distal aorta, but if the aneurysm involves the aortic bifurcation or if iliac artery aneurysmal or occlusive disease is present, a bifurcation graft is used, with the distal anastomosis to the iliac or femoral arteries. Coagulopathy is addressed and the aneurysm wall is then closed around the graft to help separate it from adjacent structures in the retroperitoneum. The bowel is re-inspected, and the abdominal wall is frequently managed with temporary abdominal closure using negative pressure wound therapy when managing ruptured aneurysms.
Endovascular Repair

More than half of all AAA repairs are now performed without laparotomy, with use of endovascular techniques. Perioperative mortality is lower than that with open repair, but it is unclear whether this mortality benefit is sustained in the long-term. More recent studies suggest the survival advantage is maintained for 3 years. Numerous studies have cited a clear reduction in early mortality associated with endovascular aneurysm repair (EVAR) but continue to emphasize the importance of an organized algorithmic approach with a specialized team. Hemodynamically stable patients undergo rapid 64 slice CTA with three-dimensional reformatting. Although many hospitals have hybrid operating rooms, EVAR can be done with portable fluoroscopy in the operating room.

Stable patients can undergo bilateral femoral artery cut-downs to place sheaths and wires once in the operating room. Unstable patients, however, may require transfemoral access with a 12 French sheath followed by aortic balloon occlusion in the ED. Once an arteriogram is performed with a marking flush catheter, the endovascular plan is formulated unless a contrast enhanced CT scan is available for stent sizing.

A stent graft (a fabric graft supported by a nitinol wire frame) is placed into the femoral artery percutaneously or through a groin incision and is advanced under fluoroscopic guidance to a position that spans the infrarenal aneurysm (Fig. 76.6A). The contralateral iliac limb is placed to form a bifurcated graft (see Fig. 76.6B). Once in position, the graft is deployed and expanded to fit tightly against the walls of the aorta. These self-expanding devices have radial forces but are also oversized 10% to 20% to ensure proper sealing. There are several devices approved by the U.S. Food and Drug Administration (FDA) and all have unique features. Standard criteria for use include an aortic transverse diameter between 18 to 32 mm, angulation less than 60 degrees, and neck (lowest renal artery to start of aneurysm) length more than 10 mm, iliac landing zone diameter of 10 to 22 mm, and femoral access diameter more than 8 mm.

Endovascular repair results in more frequent reinterventions for graft-related complications. Because not all aneurysms are anatomically suitable for endovascular repair, detailed preoperative imaging and planning are required to make this determination. In addition, patients who have had endovascular aneurysm repair remain at risk for several complications—most importantly rupture of the aneurysm. Some authors now suggest that endovascular repair has become the first choice of AAA treatment in almost all patients with anatomical condition, remaining the most important factor for indication for open repair. Lack of inventory and expert local experience with endovascular operations remain the greatest barrier to the widespread application of evolving endovascular technologies for emergency use. Percutaneous endovascular repair is becoming more common and may represent a suitable alternative to open endovascular repair in some patients.

Survival

The operative mortality rate for elective AAA repair is approximately 1% to 2% for endovascular repair and 3% to 5% for open repair, in contrast to the much higher operative mortality with ruptured aneurysms. Patients who survive the operation have an excellent prognosis, with a long-term survival close to that of the general population. After repair of the aneurysm, long-term survival is primarily limited by associated cardiac disease.

LATE COMPLICATIONS OF REPAIR

Graft infection, AEF formation, and anastomotic aneurysm (pseudoaneurysm) formation can occur at any time from weeks to years after the surgery. These complications can occur concurrently or sequentially and are diagnosed by similarly. In addition, endovascular aneurysm repair has several unique complications, the most important of which is endoleak.

Graft Infection

Graft infection can result from contamination of the graft at surgery, spread of a contagious infection, or hematogenous seeding. Infection can disrupt the anastomosis between native artery and graft, leading to leakage of blood from the anastomosis and pseudoaneurysm formation. The infection can be localized to a portion of the graft, most often the inguinal portion of an aortofemoral graft, or can involve the entire graft. Infection of the distal limb of an aortofemoral graft may cause local signs of infection or a palpable false aneurysm. Intraabdominal graft infection is often subtle, with low-grade fever and vague abdominal or back pain. Abdominal tenderness or a palpable mass may be present if there is a leaking anastomosis. Collections of fluid or gas around the graft on CT provide evidence of infection, although CT scans can be falsely negative.
Aortoenteric Fistula
As discussed earlier in this chapter, an AEF should be considered in any patient with gastrointestinal bleeding and a history of abdominal aortic surgery. Most of these patients, however, ultimately prove to have other, more common causes of gastrointestinal bleeding. The diagnostic approach depends on the patient’s hemodynamic stability.

If the patient with a suspected AEF is unstable with massive bleeding, diagnostic testing may be dangerously time-consuming. In these patients, emergency laparotomy may be necessary to control hemorrhage and diagnose or exclude the presence of an AEF. Stable patients can be evaluated with endoscopy or a CT scan. Some patients with AEF may be treated endovascularly, which may result in improved perioperative morbidity and mortality.

Upper gastrointestinal endoscopy is occasionally recommended as the initial diagnostic test. Direct visualization of the fistula into the distal duodenum is sometimes possible. Endoscopy cannot be relied on to identify an AEF, however, and its main value is in establishing another diagnosis. Emergency surgery can be avoided if an active bleeding site that is not an AEF is clearly seen.

An abdominal CT scan can also be used to evaluate a suspected AEF. Although imaging of the fistula may not be possible, graft infection is almost invariably present in patients with secondary AEFs, and the CT scan will demonstrate the associated infection. Radiographically distinguishing an AEF from intra-abdominal graft infection alone may not be possible.

Pseudoaneurysm (Anastomotic Aneurysm)
Pseudoaneurysms can arise at the site of a leaking anastomosis. They may be associated with graft infection or AEF formation but more often result from degeneration of the native vessel.

The patient with an anastomotic aneurysm may have pain or a pulsatile mass in the abdomen or groin. The aneurysm may give rise to distal emboli or may rupture and cause life-threatening hemorrhage. Suspected pseudoaneurysms can be evaluated with angiography, CT scan, or ultrasonography.

Complications of Endovascular Aneurysm Repair
A rapidly increasing percentage of elective AAA repairs are done with endovascular techniques, and these patients may come to the

![Fig. 76.7. Types and causes of endoleaks. (From Greenhalgh RM, Powell JT: Endovascular repair of abdominal aortic aneurysm. N Engl J Med 358:494-501, 2008. Copyright © 2008, Massachusetts Medical Society. All rights reserved.)]
ED with postoperative complications. The most serious of these is endoleak—blood flow outside of the graft lumen but within the aneurysm sac, potentially allowing enlargement of the aneurysm. Endoleaks may be caused by separation of the proximal or distal end of the graft from the aortic wall (type I), back-bleeding into the aneurysm sac from branch vessels such as lumbar arteries (type II), leakage between the modular components of the graft (type III), leakage through the graft fabric itself (type IV), or in rarer cases when the sac enlarges without an identifiable leak, otherwise known as endotension (type V) (Fig. 76.7). Patients with persistent leakage of blood into the aneurysm sac are at significant risk for rupture of the aneurysm.12

Endoleaks may develop soon after the procedure or much later. They have been reported in as many as 20% of patients who have had endovascular aneurysm repair. Because many type II endoleaks resolve spontaneously, patients are sometimes observed for months before repair of the leak with secondary endovascular procedures or surgical intervention.

Patients sometimes sustain other complications, such as graft migration, stenosis or thrombosis, and structural failure of various elements of the graft. These complications often lead to endoleak and the risk of rupture.

In the ED, CT with intravenous contrast should be used to evaluate for possible complications of endovascular repair. A specific CT imaging protocol may be desired; this should be discussed with the radiologist or vascular surgeon. Prompt surgical consultation should be obtained for patients with any symptoms that could be related to device malfunction, and the potential for aneurysm rupture should always be considered.

**DISPOSITION**

A patient with an acutely symptomatic AAA requires emergency surgical evaluation and emergency repair. A patient whose aneurysm is asymptomatic and discovered incidentally should be referred for consideration of elective repair. The patient with an AAA should be referred for an outpatient evaluation only if it is clear that the symptoms prompting the ED visit are unrelated to the aneurysm. Although the incidental detection of AAA is common, such patients may suffer from poor subsequent follow-up and monitoring.4 If the patient is discharged, appropriate referral for follow-up is crucial, and instructions should be given to seek immediate medical attention if abdominal, back, or flank pain develops.

In the patient who has had an AAA repaired, unexplained fever, abdominal pain, or gastrointestinal bleeding suggests the presence of a graft-related complication and the need for inpatient evaluation.

**KEY CONCEPTS**

- A ruptured AAA should be considered in any patient older than 50 years with otherwise unexplained abdominal or back pain. The complete triad of pain, hypotension, and a pulsatile mass may not be present.
- In the patient with an AAA and acute symptoms, rupture is imminent or has already occurred.
- The patient with a ruptured AAA who is initially hemodynamically stable can suddenly deteriorate at any time.
- The risk of rupture increases dramatically with increased aneurysm size, and most ruptured AAAs have diameters greater than 5 cm.
- Bedside ultrasound may be used to document an AAA or free fluid and assist in rapid diagnosis of a ruptured AAA.
- The abdominal CT scan is the diagnostic test of choice in the evaluation of the stable patient with suspected ruptured AAA; intravenous contrast is not essential in emergency situations.
- The patient who has had endovascular repair of an AAA remains at risk for aneurysm rupture.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
A 79-year-old man presents with syncope. The episode occurred 1 hour before arrival, without preceding symptoms. The family reports a past history of peptic ulcer disease controlled with medications and a surgical repair of an abdominal aortic aneurysm (AAA) 15 years ago. Physical examination reveals a pale man with a heart rate of 115 beats per minute, blood pressure of 83/54 mm Hg, and respiratory rate of 22 breaths per minute. Other pertinent findings are an abdominal examination without palpable masses and gross melena on rectal examination. Concurrent with volume resuscitation, what would be the most appropriate next step?
A. Addition of albumin to crystalloid infusion
B. Computed tomography (CT) scan of the abdomen with contrast enhancement
C. Immediate gastrointestinal service consultation for upper endoscopy
D. Immediate vascular surgical consultation

Answer: D. The presence of gastrointestinal bleeding with a history of aortic surgery or current evidence of an AAA is an aortoenteric fistula (AEF) until proven otherwise. The most common site of vascular bowel erosion is the third or fourth portion of the duodenum, causing hematemesis or melena. The initial bleeding may be minor, followed days to weeks later by massive bleeding. Surgical intervention is required. Although endoscopy or CT scanning might help with diagnosis, this patient is not stable enough to undergo endoscopy or for transfer to the scanner. Hypotensive patients may have to be taken to the operating room on the basis of a strong clinical presumption.

76.4. What is the strongest predictor of mortality in patients with a ruptured abdominal aortic aneurysm (AAA)?
A. Age older than 70 years old
B. Anemia on ED arrival
C. Hyperglycemia
D. Hypotension
E. Presentation more than 12 hours after symptom onset

Answer: D. Preoperative hypotension is the strongest predictor of mortality. Paradoxically, there are few data guiding volume resuscitation, fluid choices, and target blood pressures. Clearly, rapid operative or endovascular surgery is most important. Crystalloid resuscitation before repair might cause dilutional coagulopathy and clot dislodgement by raising the intraoperative pressure. Judicious volume resuscitation with early use of blood products and a target systolic pressure of 80 to 100 mm Hg is probably reasonable.
with no obvious new or acute blood. All of his discomfort is relieved by a single dose of morphine sulfate. Which of the following would be the most appropriate course of action?
A. Surgical consultation
B. Internal medicine admission for observation and intravenous antibiotics
C. Gastrointestinal consultation for early follow-up and upper or lower endoscopy
D. Emergency department (ED) observation for 6 to 8 hours with serial abdominal examinations
E. Vascular surgery clinic follow-up in 1 or 2 days

Answer: A. Watchful waiting is indicated only for asymptomatic aneurysms, regardless of the size (up to 5.5 cm). The majority of “stable” AAAs are neither painful nor tender, and the presence of both in this patient suggests imminent rupture. Although the CT scan did not detect acute blood, the safest course of action would be surgical consultation, with early or imminent rupture as the presumed source of this patient’s symptoms.

76.6. Which of the following is most common in the patient with an intact (nonruptured) 6-cm abdominal aortic aneurysm (AAA)?
A. Abdominal pain
B. Absence of any symptoms
C. Back pain
D. Lower extremity pain
E. Sensation of abdominal distention

Answer: B. Most intact AAAs are asymptomatic. They may be discovered incidentally on physical examination or a radiologic study done for other reasons or may be found in an ultrasonographic aneurysm screening program. Pain in the abdomen or back does not usually develop until the aneurysm ruptures. Perfusion of the lower extremities is usually normal in patients with AAAs.

76.7. A 67-year-old man presents with a 1-week history of mild epigastric pain. On examination, he has a blood pressure of 150/100 mm Hg; the remainder of his vital signs are normal. He has no abdominal tenderness, guarding, or palpable masses. His hemoglobin is 14.0 g/dL. A bedside ultrasound examination reveals a 4.0-cm abdominal aortic aneurysm (AAA) without evidence of rupture. Which of the following is the most appropriate next step?
A. Arrange immediate operative intervention
B. Lower blood pressure with intravenous therapy
C. Obtain abdominal computed tomography (CT) scan
D. Refer for outpatient surgical evaluation

Answer: C. The patient has abdominal pain and an AAA, and it is unclear whether the pain is caused by aneurysm rupture; there is no indication for immediate surgery, which has a higher mortality rate than that of elective repair. However, the possibility of rupture makes outpatient referral inappropriate without further investigation. Ultrasonography cannot reliably exclude aneurysm rupture; therefore, a CT scan is indicated. If the CT scan shows no evidence of rupture, a decision about the next step should be made in consultation with a surgeon. Unlike the situation with aortic dissection (see Chapter 75), there is no evidence that lowering a mildly or moderately elevated blood pressure is beneficial in the patient with an intact or ruptured AAA.
Peripheral Arteriovascular Disease

Tom P. Aufderheide

PRINCIPLES

Arteries are classified into three categories on the basis of their size and histologic features: (1) large or elastic arteries (the aorta and its immediate proximal, larger branches, including the innominate, subclavian, common carotid, and pulmonary arteries); (2) medium-sized or muscular arteries (located just distal to elastic arteries, including the common femoral, axillary, and carotid arteries); and (3) small arteries (usually <2 mm in diameter) that course in the substance of tissues and organs. This chapter considers diseases of medium and small arteries.

Arterial Anatomy

All arteries possess three layers: the tunica intima, tunica media, and tunica adventitia. As peripheral arteries diminish in caliber, these three layers become progressively indistinct and are no longer identifiable at the level of the arteriole (precapillary vessel containing smooth muscle).

The tunica intima has an inner lining of endothelial cells surrounded by subendothelial connective tissue. The single layer of continuous endothelium is a unique thromboresistant layer between blood and the potentially thrombogenic subendothelial tissues. The integrity of the endothelium is a fundamental requirement for normal structure and function of the vessel wall. Endothelial injury results in intraluminal thrombosis and contributes to atherosclerosis.

The tunica media is made up primarily of circular or spiral smooth muscle cells arranged in concentric layers. The outer limit of this layer is marked by a well-defined, external elastic membrane. The elastic content of the tunica media gives resilience to medium-sized arteries. With age, elastic fibers deteriorate, replaced by fibrous tissue. This loss of elasticity results in stretching and elongation and accounts for the progressive tortuosity and development of arterial aneurysms with aging. In addition, vascular smooth muscle cells may contribute to lipid accumulation in the vessel wall during atherosclerosis, which precipitates vasoconstriction and dilation.

The tunica adventitia is a layer of connective tissue in which nerve fibers and small, thin-walled nutrient vessels (vasa vasorum) are dispersed. Medium-sized arteries contain more nerve fibers than larger vessels, reflecting their role in the autonomic regulation of blood flow.

The peripheral arterial vascular system can be considered as a single end-organ subject to eight basic pathophysiologic processes: (1) atherosclerosis, (2) aneurysm, (3) embolism, (4) thrombosis, (5) inflammation, (6) trauma, (7) vasospasm, and (8) arteriovenous fistula. Two of these—atherosclerosis and thrombosis—are responsible for most disease.

Pathophysiology

Atherosclerosis

Atherosclerosis is a disease of large- and medium-sized muscular arteries. The basic lesion, the atheroma, or fibrofatty plaque, is a raised focal plaque within the intima; it has a lipid core covered by a fibrous cap. As the plaques increase in size and number, they progressively encroach on the lumen of the artery and the adjacent media. Atheromas compromise arterial blood flow and weaken the walls of the affected arteries.

The distribution of atherosclerotic plaques is rather constant. The abdominal aorta typically is susceptible to more atherosclerotic disease than the thoracic aorta, and aortic lesions are much more common and prominent around the ostia of major branches. Other vessels affected by atherosclerosis are the aortoiliac, femoral, and popliteal arteries; the descending thoracic aorta; the coronary arteries; the internal carotid arteries; and the circle of Willis. Upper extremities vessels are usually spared.

As atherosclerosis progresses, atheromas calcify, resulting in hard, brittle vessels. Rupture of the atheromatous plaques discharge debris, producing atheroemboli (cholesterol emboli). Ulcerated lesions produce in situ thrombosis, causing intraluminal occlusion.

Hemorrhage into the plaque may further compromise the arterial lumen. Although atherosclerosis primarily affects the intima, in severe cases, the tunica media undergoes pressure atrophy and loss of elastic tissue, with sufficient weakening to create aneurysmal dilation.

Aneurysms

A true aneurysm is an abnormal localized dilation of the intact vessel wall. With a pseudoaneurysm, the entire wall perforates or ruptures, and the extravasated blood is contained by the surrounding tissues, eventually forming a fibrous sac that communicates with the artery.

Mural and mechanical factors contribute to true aneurysm formation. The major cause of aneurysms is a weakness or defect in the integrity of the arterial wall. The only aneurysms that develop in a normal arterial segment are poststenotic aneurysms, such as with coarctation. Acceleration of flow past a narrow point creates slower flow beyond the stenosis lateral to the jet stream, producing increased lateral pressure. Aneurysmal dilation accelerates, increasing the risk of rupture as diameter increases, as described by Laplace’s law: tension (lateral pressure) in the wall of a hollow viscus varies directly with its radius (tension = pressure × radius).

The most common cause of aneurysms is severe atherosclerosis resulting from thinning and destruction of the tunica media. Atheromatous ulcers covered by mural thrombi are common.
Mural thrombi form emboli that then lodge in distal vessels. When an entire aneurysm is filled with thrombus material, arterial occlusion results.

Aneurysms cause clinical symptoms through (1) rupture with subsequent hemorrhage, (2) impingement on adjacent structures, (3) occlusion of a vessel by either direct pressure or mural thrombus formation, (4) embolism from mural thrombus, and (5) a pulsatile mass.

**Arterial Embolism**

An embolus, by definition, is a foreign body, most commonly a blood clot, carried by the blood to a site distant from its point of origin. Most emboli are detached thrombus formations or thromboemboli. Less common emboli include debris from ruptured atherosclerotic plaques, tumor debris, or foreign bodies. Unless otherwise specified, the term embolus in this chapter is defined as thromboembolus.

**Thromboembolism.** Most arterial emboli (85%) originate from thrombus formation in the heart. Left ventricular thrombus formation resulting from myocardial infarction accounts for 60% to 70% of arterial emboli. Atrial thrombi associated with mitral stenosis and rheumatic heart disease account for only 5% to 10% of arterial emboli. Coexisting atrial fibrillation, often without mitral stenosis, is present in 60% to 75% of patients with peripheral arterial embolic events because atrial fibrillation itself predisposes patients to intracardiac clotting.

Acute arterial emboli often cause distal tissue infarction. Clinical outcome depends on the amount of collateral circulation, the size of the vessel, and the degree of obstruction. Patients with long-standing atherosclerosis have well-developed collateral circulation, whereas sudden occlusion of a normal artery without collateral pathways results in severe ischemia. After acute obstruction, the embolus can propagate proximally or distally, fragment and embolize further to distal vessels, or precipitate venous thrombosis by initiating a localized inflammatory reaction.

Because vessel diameters change abruptly at branch points, embolic occlusion most often occurs at major arterial bifurcations. The common femoral artery bifurcation is the most frequent site, accounting for 35% to 50% of all cases. The smaller femoral and popliteal arteries are involved twice as often as the larger aortic and iliac vessels, which reflects the small size of most emboli.

Arterial emboli, resulting in arterial occlusion and subsequent ischemia, results in cell death producing high concentrations of potassium, lactic acid, and myoglobin in the extremity distal to the occlusion. Revascularization may result in sudden release, which can produce life-threatening hyperkalemia, metabolic acidosis, and myoglobinuria. This myonephropathic-metabolic syndrome accounts for approximately one-third of the deaths from arterial embolism after revascularization.

**Atheroembolism.** Atheroembolism refers to microemboli consisting of cholesterol, calcium, and platelet aggregates dislodged from proximal complicated atherosclerotic plaques that lodge in distal end arteries. In the central nervous system, atheroemboli cause transient ischemic attacks and strokes. In the peripheral vascular system, atheroemboli characteristically cause cool, painful, and cyanotic toes, or the blue toe syndrome.

Atheroemboli are caused by a proximally located arterial lesion, usually atherosclerotic plaques or aneurysms. Bilateral distal extremity involvement implies an aortic source, whereas unilateral atheroemboli usually arise from sites distal to the aorta. Distal lesions are most common in the femoropopliteal arteries (60%) and the aortoiliac arteries (40%). Aortic lesions (eg, aneurysms, polytetrafluoroethylene grafts) are a less common source of microemboli. Atheroemboli are small (100 to 200 µm in size). Single atheroembolic events seldom result in tissue loss, but atheroemboli tend to cluster. If unrecognized, repeated events ultimately result in loss of collateral circulation, progressive symptoms, and extensive tissue infarction.

Infectious emboli from bacterial endocarditis can produce septic infarcts that may convert to large abscesses. Rarely, cardiac and noncardiac tumors or foreign bodies may gain access to the arterial circulation and embolize. Primary or metastatic lung neoplasms, malignant melanoma, and bullet emboli have been reported. With cyanotic congenital heart disease (eg, patent foramen ovale), venous emboli may pass directly to the arterial circulation (paradoxical emboli). Although rare, this possibility should be considered in any patient with simultaneous arterial and venous emboli, particularly if a source of the arterial embolus is not evident.

**Arterial Thrombosis**

Thrombosis is the in situ formation of a blood clot within the uninterrupted arterial vascular system. Complicated atherosclerotic plaques are usually responsible for the two major factors that cause in situ thrombosis: endothelial injury and alterations in normal blood flow. Less common causes include acute vasculitis and trauma. Thrombosis is rare in normal arteries.

Peripheral arterial thrombi are usually occlusive, firmly attached to the damaged arterial wall, and infrequently embolize. Clot propagation intensifies ischemia.

**Inflammation**

Inflammatory arterial injury can be caused by drugs, irradiation, mechanical trauma, or bacterial invasion. The major cause of arteritis is noninfectious systemic necrotizing vasculitis. Infectious arteritis is caused by direct invasion of the arterial wall. Septicemia, intravenous drug abuse, or infective endocarditis is most often responsible. Certain fungal infections, particularly aspergillosis and mucormycosis, are frequently associated with vasculitis and thrombosis.

**Trauma**

Vascular trauma results in characteristic pathologic syndromes. Partial arterial lacerations continue to bleed because the intact portion of the vessel wall prevents retraction and closure of the arterial wound. This may form an expanding hematoma. Complete arterial transection usually has only moderate or insignificant bleeding because of arterial spasm of the transected ends and formation of a temporary thrombus. Delayed hemorrhage results from relaxation of arterial spasm, liquefaction of the thrombus, or displacement of the thrombus by arterial pressure. Blunt injury produces intimal disruption. Dissection then leads to progressive obstruction and thrombosis. Vasospasm can accompany injuries adjacent to traumatized blood vessels; spontaneous resolution always occurs in the absence of arterial disruption or intimal injury.

**Vasospasm**

Vasospastic disorders (Raynaud’s disease, Raynaud’s phenomenon, livedo reticularis, acrocyanosis, erythromelalgia) produce an abnormal vasomotor response in distal small arteries. The cause is unknown but may be related to autonomic innervation of peripheral arterioles. Vasospastic disorders are characterized by the presence of ischemic symptoms and absence of tissue loss.
True organic changes within the arterial wall are absent. In contrast, patients with digital ulceration and gangrene always have fixed arterial occlusions in distal extremity arteries.

Arteriovenous Fistulae

Abnormal communication between arteries and veins may result from congenital defects, arterial aneurysm rupture into an adjacent vein, penetrating injuries, and inflammatory necrosis. The artery proximal and veins distal to the fistula become distended, tortuous, and aneurysmal. Proximal and distal veins respond to alterations in hemodynamics with intimal proliferation and fibrosis, followed by a decrease in the internal elastic lamina, resulting in distention, tortuosity, and aneurysm formation. Chronic venous hypertension causes dermatitis and ulceration of overlying skin. The size of the fistula generally increases with time. Approximately 60% of arteriovenous fistulae are associated with a false aneurysm. False aneurysm formation can occur as part of the fistulous tract or arterial or venous dilation. Increase in cardiac output results in tachycardia, widened pulse pressure, or high-output failure.

**CLINICAL FEATURES**

### History

Patients with peripheral arterial disease have pain, are at risk for tissue loss (ulceration or gangrene), or a change in sensation or appearance (swelling, discoloration, or temperature change). Related conditions providing evidence of atherosclerosis are cardiac disease, myocardial infarction, cardiac dysrhythmias (eg, atrial fibrillation), stroke, transient ischemic attacks, and renal disease. Factors that increase the likelihood of atherosclerosis are cigarette smoking, diabetes, hypercholesterolemia, and hypertension. Intravenous drug use can lead to arterial injury.

Risk factors unrelated to atherosclerosis include prior injuries or surgeries, a history of phlebitis or pulmonary embolism, autoimmune disease, arthritis, or coagulation abnormalities.

### Acute Arterial Occlusion

Patients with acute arterial occlusion usually exhibit some variant of the five Ps: pain, pallor, pulselessness, paresthesias, and paralysis. Paresthesias and paralysis indicate limb-threatening ischemia requiring emergency surgical intervention regardless of the cause. In patients with non–limb-threatening ischemia, accurate differentiation between embolism and in situ thrombosis determines management. Arterial embolism is best managed by emergency Fogarty catheter embolectomy. Non–limb-threatening ischemia from in situ thrombosis is often aggravated by emergency surgical intervention and is initially best managed nonoperatively if possible (Fig. 77.1). Because acute arterial embolism usually occurs in patients without significant peripheral atherosclerosis or well-developed collateral circulation, it usually manifests as sudden limb-threatening ischemia. Patients describe a sensation of the leg’s being “struck” by a severe shocking pain. Often the patient has to sit or fall to the ground during the sudden event.

In situ thrombosis usually occurs with long-standing peripheral atherosclerosis and well-developed collateral circulation, often seen sub-acutely with non–limb-threatening ischemia. A history of claudication is common with in situ thrombosis and rare with arterial embolism.

### Chronic Arterial Insufficiency

Chronic arterial insufficiency causes two characteristic types of pain: intermittent claudication and ischemic pain at rest. The location of arterial occlusion determines the location of claudication. Calf claudication is associated with femoral and popliteal disease, typically a cramping pain, reliably reproduced by the same degree of exercise and completely relieved by rest (usually 1 to 5 minutes). Aortoiliac occlusive disease causes claudication in the buttocks and hips, as well as the calves. The calf pain in aortoiliac disease is generally more severe than the buttock and thigh pain, which is more often described as an acheing, discomfort, or weakness. Some patients deny pain, complaining only that the thigh or hip “gives out” with exercise. Aortoiliac occlusive disease severe enough to produce bilateral claudication is almost always associated with impotence in men (Leriche’s syndrome). Even in the absence of impotence, bilateral hip or thigh pain in a man should indicate the possibility of aortoiliac occlusive disease.

Chronic arterial insufficiency may progress so that ischemic pain occurs at rest. Rest pain often begins in the feet and typically involves the foot distal to the metatarsals, awakening the patient from sleep. Ischemic rest pain is a severe, unrelenting pain aggravated by elevation and relieved by analgesics. Patients have prompt relief with any activity involving a standing position. Patients often sleep in a chair or with the leg dangling over the bed.

### Physical Examination

A systematic assessment of the peripheral vascular system includes palpation of the pulse volume in the pairs of brachial, radial, femoral, posterior tibial, and dorsalis pedis arteries documented on a scale of 0 to 4+. Important to note, approximately 10% of the population does not have one of the dorsalis pedis pulses. Carotid arteries should be gently palpated one at a time.

The lower extremities should be examined for signs of chronic and advanced ischemia. Muscular atrophy, particularly in the lower extremities, and loss of hair over the toes and feet with thickening of the toenails resulting from slowness of nail growth
Arterial Embolism

The physical examination can differentiate arterial embolism from in situ thrombosis. Sudden loss of a pulse is the hallmark of arterial embolism but may be difficult to recognize if prior pulse status is unknown or is abnormal because of atherosclerosis. A bounding pulse may be felt initially at the location of an embolus from transmitted pulsations through the fresh clot. Patients with arterial embolism have few physical findings suggestive of long-standing peripheral vascular disease. Tenderness to palpation may occur at the site of an embolic occlusion.

If arterial embolism is suspected, the physical examination should be directed toward identifying its source (a left ventricular mural thrombus [prior myocardial infarction] or a left atrial thrombus [mitral valve disease]). Coexistent arterial fibrillation is common.

The limb distal to an embolic occlusion is initially chalk white. Because of absence of blood in the sub-capillary venules, demarcation between ischemic and nonischemic tissue is sharp. With time, cyanosis appears from desaturation of blood with continued ongoing ischemia. Paresthesia or paralysis indicates limb-threatening ischemia. Presence of sensitivity to light touch is the best guide to viability of the tissue. Complete anesthesia demands emergent surgical intervention. Paralysis represents severe muscle and neural ischemia, which may be irreversible. Involuntary muscle contracture with “woody” hardness represents irreversible ischemia.

Arterial Thrombosis

Physical findings of in situ thrombosis are often accompanied by evidence of atherosclerotic occlusive disease. Proximal or contralateral limb pulses are usually diminished or absent. An embolic source, such as atrial fibrillation, is usually absent. Because of collateral circulation, demarcation of limb ischemia is less well defined in these patients (Table 77.1).

Carotid, renal, and femoral arteries may have bruits, and there may be an abdominal aortic aneurysm. If an occlusion of the upper extremity vessels is suggested, the subclavian artery should palpitated for thrills and auscultated for bruits in the supraclavicular fossa.

A funduscopic examination may yield evidence of arteriosclerosis or hypertension. Hollenhorst plaques (atheromatous emboli containing cholesterol crystals in the retinal arterioles) may be detected. Roth’s spots (round or oval white spots seen near the optic disk) may be present in patients with infective endocarditis.

Embolic phenomena can cause diverse end-organ damage: hemiplegia from cerebral emboli, flank pain with hematuria from renal emboli, left upper quadrant abdominal pain from splenic infarcts, and pleuritic pain with hemoptyis from pulmonary emboli. Septic pulmonary embolism from right-sided endocarditis may be confused with pneumonia.

| TABLE 77.1 |
| Differentiation of Embolus From Thrombosis |
| **CLINICAL FINDINGS** | **EMBOLUS** | **THROMBOSIS** |
| Identifiable source for embolus | Usual, particularly atrial fibrillation | Less common |
| History of claudication | Rare | Common |
| Physical findings suggestive of occlusive disease | Few; proximal and contralateral limb pulses normal | Often present; proximal or contralateral limb pulses diminished or absent |
| Demarcation of ischemia | Sharp | Diffuse |
| Arteriography | Minimal atherosclerosis; sharp cutoff; few collaterals | Diffuse atherosclerosis; tapered, irregular cutoff; well-developed collaterals |

Inflammation

Inflammatory vascular disease manifests primarily as skin involvement. Skin lesions typically appear as palpable purpura; other cutaneous manifestations of vasculitis include macules, papules, vesicles, bullae, subcutaneous nodules, ulcers, and recurrent or chronic urticaria. Skin lesions may be pruritic or painful, with a burning or stinging sensation. Lesions are more common in dependent areas: lower extremities in ambulatory patients or sacral area in bedridden patients. Edema and hyperpigmentation occur in areas of recurrent or chronic lesions.

Vasospasm

Vasospastic disorders cause a sharp border between ischemic and normal tissue. Raynaud’s disease is characterized by intermittent attacks of triphasic color changes: pallor, cyanosis, and then rubor. The most important element is pallor, during which the digits turn chalk white. Attacks last 15 to 60 minutes, and rewarming the hands restores normal color and sensation. Color changes do not occur above the metacarpophalangeal joints and rarely involve the thumb.

Livedo reticularis causes persistent cyanotic mottling of the skin with a typical “fishnet” appearance and may involve all parts of the extremities and trunk. Acrocyanosis, the least common vasospastic disorder, causes persistent, painless, diffuse cyanosis of the fingers, hands, toes, and feet. Cyanosis intensifies with exposure to cold and decreases with warming. The involved parts are cold, exhibit excessive perspiration, and have normal arterial pulses.

Arteriovenous Fistulae

Arteriovenous malformations and fistulae, although rare, should be distinguished from vascular bruises or aneurysms. True aneurysms and arterial stenoses are associated with a systolic murmur. Pseudoaneurysms have a loud systolic and sometimes a separate faint diastolic murmur. Arteriovenous fistulae have a constant systolic and diastolic (to-and-fro) murmur associated with a palpable thrill, similar to a dialysis arteriovenous fistula. Arteriovenous fistulae can occur at prior operative or trauma sites. Skin overlying the lesion may be warm, but distally the temperature is decreased. Peripheral veins are distended and varicose. Large arteriovenous fistulae produce high cardiac output and widened pulse pressure. Digital pressure on the artery leading to the fistula may decrease the tachycardia (Branham’s sign).

Differential Diagnosis

The differential diagnosis related to peripheral arteriovascular diseases can be extensive, requiring consideration of dermatologic, neurologic, neurosurgical, orthopedic, cardiac, malignant, diabetic, infectious, and other unrelated diagnoses.

Diagnostic Testing

An accurate diagnosis of peripheral arterial occlusive disease can be achieved in most patients by careful history and physical examination supplemented by bedside testing.

Noninvasive Assessment

Doppler ultrasonography measures blood flow velocity, detecting the frequency shift of sound waves reflected from red blood cells moving toward and away from the transducer. Doppler waveform analysis detects occlusive disease but is less accurate determining exact location.

Ultrasound is useful in detecting and evaluating atherosclerotic plaques, mural thrombi, and in sizing aneurysms of the abdominal aorta, iliac, femoral, and popliteal arteries. B-mode ultrasonography is noninvasive, painless, less expensive than other modalities, and universally available and is the diagnostic procedure of choice for the initial evaluation of the size of peripheral artery aneurysms. Bedside ultrasound can lead to rapid diagnosis of life-threatening conditions and reduce the number of delayed or invasive diagnostic procedures. B-mode duplex ultrasonography combines B-mode ultrasonography images and sophisticated online computer analysis of Doppler waveforms to allow simultaneous acquisition of both the image of a vascular structure and the characteristics of blood flow velocity within it. Duplex scanning permits noninvasive diagnosis of peripheral vascular, cerebrovascular, and venous disease.

Color imaging of blood flow combined with duplex scanning is known as color-coded Doppler, Doppler angiography, or angiodynography. The procedure of choice for most conditions, it allows noninvasive and accurate detection of atherosclerotic plaques and stenoses, their effect on intraluminal blood flow, and the presence of venous thrombosis.

Contrast Arteriography

Angiography is the definitive test of abnormal peripheral artery anatomy but is inconclusive about the physiologic condition of the tissues. The risk/benefit ratio of this procedure should be considered. Contrast media have direct toxic effects on vascular endothelium; can produce renal failure, especially in diabetic patients; may cause peripheral vasodilatation with hypotension; may result in seizures and stroke in patients with neurologic conditions; and can cause severe idiosyncratic and allergic reactions. Catheter-related complications, including embolization, catheter breakage, and vascular disruption, vary with operator skill and anatomic location but average 0.5%. Overall mortality rate from angiography is 0.03%. Emergency angiography is usually necessary in the following circumstances: (1) acute arterial embolus or thrombosis if the clinical diagnosis is uncertain, (2) consideration of emergency vascular bypass grafting, and (3) characterization of vascular abnormality before emergency surgical correction.

Computed Tomography and Magnetic Resonance Imaging

Computed tomography angiography (CTA) is the most useful test for evaluation of the abdominal aorta. In the peripheral arteriovascular system, CTA is useful for atherosclerotic, infected, and false aneurysms and the cerebral circulation. Magnetic resonance imaging (MRI) with angiography (magnetic resonance angiography) and has been very useful in delineating cerebrovascular problems (see Chapter 101); it is seeing expanded use in the evaluation of peripheral vascular disease. MRI detects changes in the relaxation variables of tissues before obvious structural changes, uniquely differentiating blood, thrombus, fat, and fibrosis.

Management

The management of acute arterial occlusion depends on the degree and cause of ischemia. Patients with limb-threatening ischemia from embolism should undergo emergency Fogarty catheter embolectomy. Patients with limb-threatening ischemia from in situ thrombosis require direct or Fogarty catheter thrombectomy and vascular bypass grafting. Thrombectomy alone often fails because of recurrent thrombosis. Patients who cannot be bypassed, have irreversible ischemia, or are too ill to tolerate revascularization are treated with primary amputation.
A patient with non–limb-threatening embolism is still treated with Fogarty catheter embolectomy. Non–limb-threatening in situ thrombosis is managed nonoperatively with emergent systemic anti-coagulation and consideration of intra-arterial fibrinolytic therapy (see Fig. 77.1).

Elective surgical repair of asymptomatic atherosclerotic peripheral arterial aneurysms is accomplished by aneurysm excision with end-to-end anastomosis or graft interposition. Infected true and false peripheral aneurysms require aneurysm resection, débridement of infected tissue, and ligation of the proximal and distal uninfected arteries. Autogenous vein bypass through uninfected tissue planes is attempted; there is high risk of prosthetic graft infection. The surgical approach for uninfected false aneurysms is similar to peripheral atherosclerotic aneurysms.

Patients with thoracic outlet syndrome who have cervical ribs, arterial involvement, or neurologic symptoms require surgical decompression, removal of anomalous fibromuscular bands, or resection of the first rib if present. Subclavian axillary aneurysms are treated with resection and end-to-end anastomosis or graft interposition. Patients with distal embolic occlusions receive Fogarty catheter embolectomy. Axillary and subclavian vein thromboses are best managed with surgical thrombectomy or systemic fibrinolytic therapy. Brachial plexus involvement with minimal symptoms is followed closely with conservative treatment.

Surgical treatment of peripheral arteriovenous fistulae requires interrupting the fistula tract and restoring both arterial and venous continuity with end-to-end anastomosis or graft interposition. If the anatomic location precludes surgical intervention, percutaneous transvascular embolization with liquid tissue adhesives (eg, isobutyl 2-cyanoacrylate) is usually successful.

### Noninvasive Therapy

#### Acute Anticoagulation With Heparin

For acute arterial embolism, acute arterial thrombosis, and subclavian vein thrombosis, heparin is indicated at standard intravenous doses (80 units/kg bolus, followed by a maintenance infusion of 18 units/kg/hr). Heparin minimizes clot propagation, which can intensify limb ischemia and jeopardize tissues. Relative contraindications include recent neurosurgery (especially within 2 weeks), major surgery within 48 hours, childbirth within 24 hours, a known bleeding diathesis, thrombocytopenia, a potentially hemorrhagic lesion, and active bleeding.

#### Fibrinolytic Therapy

Low-dose intra-arterial fibrinolytic therapy is increasingly used for acute arterial occlusion. Patients with limb-threatening ischemia are usually not candidates, because they cannot tolerate the time to achieve clot lysis with this approach (6 to 72 hours) without risk of tissue or limb loss. Fibrinolytic therapy is reserved for patients with in situ thrombosis and non–limb-threatening ischemia.

Intra-arterial fibrinolytic agents induce clot lysis in small, distal runoff vessels, decreasing outflow resistance and enabling the native artery to remain open longer. Fibrinolysis often uncovers a critical stenosis that, untreated, may lead to recurrent thrombosis. After successful fibrinolytic therapy, most patients require secondary bypass grafting or angioplasty. Streptokinase, urokinase, and tissue plasminogen activator have all been used successfully. Intravenous administration of a fibrinolytic agent is less effective than direct administration into the clot. Clots more than 30 days old are less likely to achieve successful lysis.

### Invasive Therapy

#### Fogarty Catheter Thrombectomy

The Fogarty catheter is most frequently used for iliac, femoral, and popliteal embolectomy, often with only local anesthesia. Aortic saddle embolus is removed by sequentially passing the Fogarty catheter through bilateral common femoral arteriotomies. Newly formed in situ thrombosis may often be successfully removed with the Fogarty catheter. An older thrombus adheres more firmly to the damaged vessel wall, requiring direct surgical thrombectomy. The Fogarty catheter is not used in the venous system because of valves.

#### Peripheral Percutaneous Transluminal Angioplasty

The initial success and long-term patency achieved with angioplasty depend on the location of the lesion and the extent of atheromatous disease. Proximal larger arteries (eg, iliac, femoropopliteal) have the best initial and long-term results. Discrete stenotic lesions (<5 cm) have better long-term patency rates than vessels with diffuse involvement. Balloon angioplasty is the accepted treatment for isolated stenoses in the renal, iliac, and superficial femoral vessels.

Transluminal angioplasty with intravascular stent is used in more distal vessels, including the popliteal and tibial circulation, in cases of more diffuse lesions, and for patients who are prohibitive surgical risks, although its value continues to be assessed. Recanalization devices include the percutaneous atherectomy catheter, percutaneous angioscope, hot-tip laser, excimer laser, and high-speed rotating wire and drill.

#### Grafting

Vascular grafting is associated with a variety of complications that can be diagnosed in the emergency department. Autogenous vein grafts (usually a reversed greater saphenous vein) provide excellent long-term patency for small arteries. They may develop atherosclerosis, which can lead to graft stenosis and thrombosis. False aneurysms can form along the suture line. Polytetrafluoroethylene (Teflon) prosthetic grafts are used in medium and large arteries impossible to bridge with smaller vein grafts. Prosthetic grafts have higher rates of thrombosis than venous grafts. Distal emboli result from poor fixation of luminal fibrin. Prosthetic grafts not adequately covered by viable tissue can erode into adjacent structures and hollow viscera. Prosthetic graft infection, a devastating complication, necessitates removal of the entire graft. Vascular grafts can be used to bypass arterial occlusions, reconstruct a diseased arterial bifurcation, or can be interposed between sections of resected artery. The most common complications of both prosthetic and vein grafts are thrombosis and development of a false aneurysm at one or more suture lines. Bypass grafting is most often used as palliative treatment for symptoms of atherosclerotic occlusive disease. Patients with localized unilateral stenosis may have comparable rates of success from angioplasty with or without stent placement.

Patients with calf claudication from superficial femoral or popliteal occlusive disease can slow progression if they stop smoking and maintain an active exercise regimen. Patients who have progression of disease, significant rest pain, or tissue loss require surgical revascularization.

#### Sympathectomy

Lumbar sympathectomy is no longer used for treatment of ischemia from arterial occlusion. The benefit of sympathectomy for
symptomatic Raynaud’s phenomenon is unclear, but it remains a potential intervention for ischemic ulcers and rest pain in patients with Buerger’s disease.27

**Hyperbaric Therapy**

Scant objective evidence indicates that hyperbaric therapy alters the long-term course of chronic obliterative vascular disorders, presumably by accelerating formation of new vessels. More success has been achieved with healing chronic diabetic ischemic ulcers and salvaging ischemic skin grafts and flaps.28 Referral to a hyperbaric unit for chronic therapy should be made by the patient’s primary physician or vascular surgeon and not in the emergency department.

**DISPOSITION**

Disposition of most patients with a suspected or confirmed peripheral arteriovascular diagnosis should be made in consultation with a vascular surgeon.

**SPECIFIC ARTERIOVASCULAR DISEASES**

**DISEASES OF CHRONIC ARTERIAL INSUFFICIENCY**

**Arteriosclerosis Obliterans**

Arteriosclerosis obliterans (atherosclerotic occlusive disease, chronic occlusive arterial disease, obliterative arteriosclerosis) is the peripheral arterial presentation of atherosclerosis. Most often, arteriosclerosis obliterans affects the lower abdominal aorta, the iliac arteries, and the arteries supplying the lower extremities. Upper extremity manifestations are rare.

Arteriosclerosis obliterans is responsible for 95% of cases of chronic occlusive arterial disease. It is most common in persons older than 50 years, but as many as 19% of cases occur in patients 30 to 49 years old. Men are affected more often than women (5:1 to 10:1). Approximately one-third of patients with arteriosclerosis obliterans have coexistent coronary artery disease. The incidence of diabetes mellitus is 20% to 30%.19

Risk factors for arteriosclerosis obliterans include cigarette smoking, hyperlipidemia, and hypertension. Of patients with arteriosclerosis obliterans, 70% to 90% are smokers when first examined, 75% have hyperlipidemia, and 30% have hypertension.19

**Clinical Features and Differential Diagnosis**

Acute arterial occlusion from embolism, thrombosis, or trauma is ruled out primarily by history. Atheromatous emboli from proximal ulcerated plaques or aneurysms cause small scattered ischemic lesions in the toes, feet, or legs, causing blue toe syndrome (Fig. 77.2). Peripheral pulses are present. Exercise-induced claudication needs to be distinguished from nocturnal muscle cramps frequently seen in elderly patients. Aortoiliac occlusive disease can be differentiated from osteoarthritis of the hip, which tends to be more variable from day to day, is not relieved completely with rest, and is not reliably reproduced by the same amount of exercise. Pseudoclaudication from the cauda equina syndrome is caused by narrowing of the lumbar canal from spondylosis, intervertebral disk disease, or spinal cord tumor. The symptoms mimic intermittent claudication but are less closely related to exercise and rest than true claudication.

The cause of lower extremity ulcers should be carefully determined. Approximately 5% of lower extremity ulcerations are caused by arterial insufficiency.28 These are usually located distal to the ankle, typically at the terminal portion of the digits, around the nail beds, or between the toes, caused by friction of one toe on another. Less common locations include the metatarsal heads, heel, and malleoli. Arterial insufficiency ulcers are painful but pain improves when the extremity is in a dependent position. They are associated with evidence of coexistent chronic arterial insufficiency (absence of hair growth on the dorsum of the feet, skin atrophy, absent pulses, and nail deformities). Ulcers are initially small, shallow, and dry. The base is gray, yellow, or black, with minimal or no granulation tissue. The rim of the ulcer is sharp and indolent, showing no signs of cellular proliferation or epithelialization.

About 90% of lower extremity ulcers are caused by chronic venous insufficiency.20 These occur proximal to or in the region of the ankle, especially near the medial malleolus. Venous stasis ulcers are mildly painful and improve with elevation of the extremity. Evidence of long-standing chronic venous insufficiency, including edema, prominent superficial veins, and stasis dermatitis, is present. Ulcers are moderate in size, with a weeping base and extensive granulation tissue. Rapidly developing ulcers are more suggestive of venous insufficiency.

Most of the remaining lower extremity ulcers are caused by diabetic neuropathy, alone or with arterial insufficiency.20 The location reflects sites of repeated trauma, including the toes, heels, and plantar surface of the feet, especially the metatarsal heads. Neurotrophic ulcers are painless. Patients may have evidence of coexistent peripheral arterial insufficiency. The ulcers are deep and penetrating, often with supplicative drainage caused by an underlying infection or chronic osteomyelitis. Neurotrophic ulcers are usually surrounded by a rim of thick callus.

Hypertensive ulcers are rare and reflect long-standing, uncontrolled hypertension. These ulcers are typically near the lateral malleolus and start as painful, reddish blue areas of infarcted skin. A hemorrhagic bleb develops then breaks down into a superficial ulcer, which can reach a size of 5 to 10 cm. The ischemic ulcer has
sharp demarcated borders, little granulation tissue, and minimal drainage. The pain is the most severe of all lower extremity ulcers. Multiple ischemic ulcerations above and below the ankle suggest vasculitis or atheromatous embolization. Ulcers with regular edges in unusual locations may be factitial or may result from subcutaneous injection of illicit drugs. Thickened, rolled, and elevated edges with a central depression containing granulation tissue are characteristic of malignant ulcers.

Management
The first step is to identify patients whose symptoms are the sole result of arteriosclerosis obliterans without coexistent thromboembolic disease. Treatment for symptomatic patients depends on whether patients have functional ischemia or limb-threatening ischemia.21

Limb-threatening ischemia constitutes a surgical emergency. Angiography should be arranged to identify sufficiently localized disease to permit emergency bypass grafting.21 Patients with functional ischemia should have outpatient arrangements for elective invasive or noninvasive vascular testing to determine treatment options. Ischemic ulcers or skin lesions should be cultured in the emergency department and systemic antibiotics initiated to cover skin organisms if infection is present. Radiographs of underlying bones should be acquired when osteomyelitis is suspected. Patients with ischemic rest pain require hospitalization even if they are not surgical candidates. Bed rest, a warm environment, and maintenance of the limb in a dependent position usually relieve pain.

Buerger’s Disease (Thromboangiitis Obliterans)

Principles
First described by Buerger in 1908, thromboangiitis obliterans is an idiopathic inflammatory occlusive disease primarily involving the medium-sized and small arteries of the hands and feet.22 Patients are usually men aged 20 to 40 years old who use tobacco, although recent reports indicate an increasing frequency of this disease in women. Buerger’s disease affects people of all races but is more prevalent in the Middle and Far East.23 In the United States, incidence is 20 per 100,000.23 The exact pathogenesis is unknown, but virtually all patients are smokers. Thromboangiitis obliterans is characterized by segmental acute and chronic inflammation in the smaller arteries of both upper and lower extremities. The initial arterial inflammatory process progresses to affect the adjacent veins and nerves, often leading to associated venous thrombosis and progressive fibrous encasement of these structures. These are painful, tender, or dark nodules over a peripheral artery with either a reduced or an absent pulse (phlebitis migrans).

Clinical Features
Clinical criteria for Buerger’s disease include (1) a history of smoking, (2) onset before the age of 50, (3) infrapopliteal arterial occlusive lesions, (4) either upper limb involvement or phlebitis migrans, and (5) absence of atherosclerotic risk factors other than smoking. A characteristic symptom of Buerger’s disease is foot or instep claudication caused by infrapopliteal arterial occlusion. Intense rubor of the affected extremity, particularly with dependency, is also characteristic. Foot pulses may be absent in the presence of normal femoral and popliteal pulses. Involvement of the hands is often bilateral and symmetrical, leading to the development of hand claudication or fingertip ulcers. Phlebitis migrans occurs early in the disease. Approximately 50% of patients experience Raynaud-type triphasic color response to cold. In the upper extremities, the digital arteries are usually more involved than the radial or ulnar arteries.23

Differential Diagnosis
Arteriosclerosis obliterans is most likely in patients older than 50 years old who have signs of peripheral ischemia. In young women, autoimmune diseases, such as scleroderma or systemic lupus erythematosus, should be considered.23

Diagnostic Testing
Adherence to diagnostic clinical criteria should suffice for emergency department diagnosis of Buerger’s disease. Noninvasive vascular laboratory testing confirms the diagnosis and extent of involvement. Rarely required, angiography demonstrates multiple segmental occlusions.

Management
Permanent complete abstinence from tobacco is the only effective treatment for Buerger’s disease. If a patient does not completely stop smoking, alternating periods of quiescence are followed by exacerbations of severe arterial insufficiency. Patients who quit smoking have a benign clinical course. Despite this, many individuals who have Buerger’s disease continue to smoke, incurring severe pain at rest, tissue loss, and eventually amputation. With early symptoms without threat of tissue loss, patient education and follow-up with a vascular surgeon are sufficient. Vascular surgery treatment options are varied for patients with severe symptoms or threatened tissue loss. Intractable pain can be controlled with epidural anesthesia. Intra-arterial or intravenous prostaglandin E1 and antithrombotic agents, including aspirin and heparin, have been used successfully.23 Patients with large-vessel arterial occlusion may benefit from arterial reconstruction. Sympathectomy is a potential treatment in advanced cases for cutaneous ulceration or relief of rest pain.23 Because patients with Buerger’s disease have good healing, intensive conservative treatment is usually successful in avoiding amputation.

DISEASES OF ACUTE ARTERIAL OCCLUSION

Arterial Embolism
Despite advances, acute arterial embolus continues to cause substantial morbidity and mortality. Approximately 50% of acute arterial occlusions are caused by arterial embolism, and the incidence is increasing. The other 50% are caused by in situ thrombosis.24

Differential Diagnosis
Phleghmasia cerulea dolens is a massive iliofemoral deep venous thrombosis. The initial symptom is acute onset of a swollen and painful leg. As swelling continues, secondary arterial insufficiency with associated pallor (phlegmasia cerulea albens) occurs. Early in acute arterial embolism, leg swelling is usually absent. Acute embolism produces a sharply demarcated pallor; phlegmasia cerulea dolens causes a cyanotic-appearing leg.

Aortic dissection may involve the arteries of the upper or lower extremity and may mimic acute embolus. Severe pain, the presence of aortic insufficiency, and involvement at multiple sites suggest dissection. Neurologic syndromes (eg, transverse myelitis, spinal subarachnoid hemorrhage, ruptured intervertebral disk) may produce sudden onset of unilateral or bilateral lower extremity weakness or sensory loss that mimics an acute aortic saddle occlusion.
Cold, blue extremities may result from low-output states, such as hypovolemia, decreased cardiac output, and dehydration in patients with long-standing atherosclerotic disease.

Management

Acute arterial embolism is a surgical emergency. The likelihood of limb salvage decreases after 4 to 6 hours. On the basis of clinical diagnosis alone, full doses of intravenous heparin should be administered emergently to minimize clot propagation. Patients whose clinical findings clearly indicate an acute arterial embolism should undergo urgent Fogarty catheter embolectomy without prior angiography. In these patients, preoperative ultrasonography and angiography are rarely useful diagnostically and prolong the limb’s ischemic status.

If the differentiation of acute embolism and in situ thrombosis is uncertain, pretreatment angiography is usually diagnostic. Patients with acute emboli generally show minimal signs of atherosclerosis, occlusion at the site of an arterial bifurcation, sharply demarcated cutoffs, and lack of flow distal to the occlusion. In patients with in situ thrombosis, arteriography shows diffuse atherosclerosis, occlusion at sites other than arterial bifurcations, a tapered irregular cutoff, and well-developed collateral vessels (see Table 77.1).

Intra-arterial thrombolytic therapy for acute embolism remains investigational. Present limb-threatening ischemia precludes consideration of treatment with thrombolytic therapy in most patients. Potential risks of thrombolytic therapy in arterial embolism patients with non–limb-threatening ischemia include partial clot lysis with distal embolization or recurrent embolic events from the primary source of the initial embolus.

Atheroembolism (Blue Toe Syndrome)

Atheroemboli are microemboli consisting of cholesterol, calcium, and hemorrhagic debris that break off from proximal atherosclerotic plaques or aneurysms and lodge in distal end arteries. In the central nervous system, atheroembolism causes transient ischemic attacks and strokes. In the peripheral vascular system, atheroemboli are found in the lower extremities with cool, painful cyanotic toes in the presence of palpable distal pulses (see Fig. 77.2).

Clinical Features

The typical presentation of atheroembolism is the sudden onset of a small, cyanotic and tender area on the foot, typically the toe. If bilateral, the distribution is not symmetrical. Posterior tibial and dorsalis pedis pulses are present. Physical examination should focus on a proximal source, such as an atherosclerotic aneurysm in the aorta or iliac, femoral, or popliteal artery.

Differential Diagnosis

A variety of conditions can mimic blue toe syndrome. Acrocyanosis is painless, has a symmetrical distribution, and is located in the hands, nose, and lips. Poor peripheral perfusion from low cardiac output should be considered. Vasculitis typically causes palpable purpuric lesions and constitutional symptoms of low-grade fever and weight loss. Previous frostbite may leave the extremities sensitive to cold. Local injury to the diabetic foot is easily differentiated.

Management

Treatment is directed toward identifying and removing the proximal source of atheroembolism. Angiography is the most accurate diagnostic method for determining the source of emboli. If the source is an aortic aneurysm and the patient is a surgical candidate, operative repair should be performed. Stenotic lesions in the iliac or femoral arteries can be treated with local endarterectomy, vascular bypass, or angioplasty. Medical management with aspirin, dipyridamole, warfarin sodium (Coumadin), or steroids has variable results.

Arterial Thrombosis

Approximately 50% of acute arterial occlusions are caused by in situ thrombosis. Acute arterial thrombosis is almost always superimposed on a complicated atherosclerotic lesion but can be caused by vasculitis or trauma. With limb-threatening ischemia, angiography can be used to evaluate the feasibility of emergency bypass grafting. In non–limb-threatening ischemia, angiography may be required to distinguish acute embolism from thrombosis (see Table 77.1).

Management

Heparinization should be started when the diagnosis is made. Patients with limb-threatening ischemia require emergency direct or Fogarty catheter thrombectomy combined with bypass grafting. Thrombectomy alone often fails due to rethrombosis. Patients who have atherosclerotic disease not amenable to vascular bypass, are too ill to tolerate revascularization, or have irreversible ischemia require primary amputation. Patients with non–limb-threatening ischemia are best treated nonoperatively with heparin and low-dosage intra-arterial thrombolytic therapy.

Peripheral Arterial Aneurysms

A true aneurysm is an abnormal localized dilation of the intact vessel wall caused by mural weakness and hemodynamic forces. Aneurysms enlarge at a rate determined by the cause. Atherosclerosis etiologies progress slowly over years; trauma or infectious causes enlarge over days, weeks, or months. The primary risk of central aneurysms (abdominal aorta, iliac arteries, and visceral arteries) is rupture (see Chapter 84). Peripheral arterial aneurysms rarely rupture; instead, they are complicated by thrombosis or embolism jeopardizing distal tissues.

The cause of an aneurysm depends on its anatomic location. Lower extremity aneurysms are most often atherosclerotic. Upper extremity aneurysms are usually caused by local trauma. Visceral aneurysms are from abnormal hemodynamics, atherosclerosis, or infectious causes.

Lower Extremity

Femoral and popliteal artery aneurysms almost always occur in older men with advanced atherosclerosis. Twenty-five percent of patients have distal atheroembolism or thromboembolism; an additional 15% have total aneurysmal occlusion from in situ thrombosis.

Popliteal aneurysms are the most common peripheral aneurysms, occurring bilaterally in 60% of patients. Abdominal aortic aneurysm occurs in 80% of patients with bilateral popliteal aneurysms. Most patients have claudication, thromboembolic events, atheroembolic events, or gangrene. With aneurysmal dilation, venous compression and deep venous thrombosis occur.

Femoral aneurysms are the second most common peripheral aneurysms and manifest similarly to popliteal aneurysms. Femoral aneurysm dilation can also compress the femoral nerve, producing anterior thigh pain or weakness.

Diagnosis of popliteal and femoral aneurysms is by palpation of a pulsatile mass. Plain radiographs may show unilateral or
bilateral calcified aneurysms. Ultrasonography and CT are diagnostic. Arteriography yields definitive diagnosis and involvement of distal vessels. Patients with a lower extremity aneurysm should be evaluated for the presence of other aneurysms.

Asymptomatic patients can undergo elective surgical excision of the aneurysm and end-to-end anastomosis or graft interposition. Simultaneous repair of coexisting abdominal aorta or contralateral extremity aneurysms combined with vascular bypass is typically done. Patients with limb-threatening thromboembolic events are first treated with Fogarty catheter embolectomy.26

Upper Extremity

Atherosclerosis generally spares the upper extremities, so peripheral arterial aneurysms in the upper extremities are rare, making localized trauma the most common cause.

The causes of subclavian artery aneurysms are thoracic outlet obstruction, trauma, and, rarely, atherosclerosis. Subclavian aneurysms from atherosclerosis represent severe disease, and 30% to 50% of patients so afflicted also have aortoiliac or other peripheral aneurysms.27 Symptoms depend on the aneurysm's anatomic location. Patients may have chest, neck, and shoulder pain from acute expansion. Compression of the right recurrent laryngeal nerve can lead to voice change. Compression of the trachea can lead to stridor or other respiratory complaints. The chest radiograph may reveal a superior mediastinal mass, confused with a neoplasm.

The subclavian artery can be compressed by a complete cervical rib that articulates with the first rib, producing a poststenotic dilation in the proximal subclavian and distal axillary artery. This syndrome occurs more often in women and in the dominant upper extremity. Cervical ribs occur in 0.6% of the population.3

Axillary artery aneurysms are caused by blunt trauma from inappropriate and prolonged use of crutches. Humerus fracture or anterior shoulder dislocation are uncommon causes.27 Subclavian, subclavian-axillary, and axillary artery aneurysms share complications of thromboembolism, limb-threatening ischemia, neuromuscular and sensory dysfunction from brachial plexus compression, and central nervous system ischemia from retrograde vertebral and right carotid thromboembolism. A systolic bruit and palpable thrill is common.

Arteriography to confirm diagnosis and determine involvement of distal vessels is the diagnostic procedure of choice. Surgical treatment consists of aneurysm resection, vascular grafting, and re-establishment of arterial continuity.

The rare syndrome of ulnar artery aneurysm (hypothenar hammer syndrome) is associated with occupational trauma in which the heel of the palm is used to hammer, push, or twist objects.9 Patients are often mechanics, carpenters, or machinists.

The ulnar artery fits snugly into the bony canal at the hypothenar eminence under the hook of the hamate bone. Long-term repetitive damage results in aneurysm formation.29 The aneurysm may develop a mural thrombus that repeatedly embolizes to the superficial palmar arch or to a digital artery. Symptoms include paresthesias, pain, coolness, and cyanosis, most often in the little and ring fingers, occasionally in the middle and index fingers. The thumb is characteristically spared due to its radial artery blood supply. Diagnosis is easily made by finding a pulsatile or non-pulsatile tender mass in the hypothenar eminence of the dominant hand. The Allen test may demonstrate occlusion of the ulnar artery. Angiography of the distal vessels is diagnostic. Proximal angiography may rule out the subclavian and axillary arteries as embolic sources. Surgical aneurysm resection is required to reestablish ulnar artery continuity. Adjunctive preoperative fibrinolytic therapy may be helpful.29

Viscera

Splenic Artery Aneurysms

Splenic artery aneurysms account for 60% of all visceral arterial aneurysms. They are the only aneurysms that are more common in women, with a female-to-male ratio of 4:1.30 The cause of splenic artery aneurysms has been attributed to systemic arterial fibrodysplasia, portal hypertension, and increased splenic arteriovenous shunting that occurs in pregnancy.

Splenic artery aneurysms are most often asymptomatic. Symptomatic patients exhibit vague left upper quadrant or epigastric discomfort and occasional radiation of pain to the left shoulder or subscapular area. Because most splenic artery aneurysms are less than 2 cm in diameter, a pulsatile mass is not palpable. Occasionally, a systolic bruit can be heard.

Only 2% of splenic artery aneurysms result in life-threatening rupture.30 More than 95% of ruptures occur in young women during pregnancy and can be confused with ectopic pregnancy or placental abruption.

Splenic artery aneurysms are usually an incidental discovery on the abdominal radiograph as signet ring calcifications in the left upper quadrant. Ultrasonography, CT, and MRI can distinguish aneurysms from other cystic lesions in the left upper quadrant.28 An angiogram is usually required to confirm the diagnosis. Symptomatic splenic artery aneurysms require urgent operative intervention, particularly in pregnant women or in women of childbearing age. The rate of maternal mortality from rupture during pregnancy is approximately 70%. In asymptomatic patients, transcatheter embolization is an alternative to surgery.31

Hepatic Artery Aneurysms

Hepatic artery aneurysms represent 20% of visceral artery aneurysms. The lesions are caused by atherosclerosis, infection (most often as a complication of intravenous drug abuse), major abdominal trauma, and polyarteritis nodosa. Hepatic artery aneurysms affect men twice as often as women and usually occur after 60 years of age.

Most aneurysms remain asymptomatic, but unruptured symptomatic aneurysms generally produce symptoms consistent with cholecystitis: vague, persistent, right upper quadrant, or epigastric pain radiating to the back. Large aneurysms can cause severe upper abdominal discomfort, similar to pancreatitis. Hepatic artery aneurysms may rupture into the common bile duct, peritoneum, or adjacent hollow viscera, with a mortality rate of 35%.

An abdominal bruit or palpable pulsatile mass is usually not present on physical examination. Aneurysmal calcification may be seen on a plain abdominal radiograph, but the diagnosis can be made reliably by angiography. Ultrasonography and CT can detect asymptomatic hepatic artery aneurysms.30 Because of the high mortality rate with aneurysmal rupture, an aggressive approach to management is warranted. Surgical resection of the aneurysm is performed in operative candidates. Transarterial catheter occlusion can be used in patients who are high surgical risks.32

Superior Mesenteric Artery Aneurysms

Superior mesenteric artery aneurysms are the third most common visceral aneurysms. Nearly 60% are infected aneurysms caused by nonhemolytic streptococci from left-sided bacterial endocarditis. Atherosclerosis and trauma are much less common causes. Patients are usually younger than 50 years old; men and women are affected equally.

Patients generally have intermittent upper abdominal pain consistent with abdominal angina. Fifty percent have a pulsatile
abdominal mass on physical examination. The stigmata of subacute bacterial endocarditis may be present. Plain abdominal radiographs may show a calcified aneurysm. Angiography is necessary to confirm the diagnosis.

Management of superior mesenteric artery aneurysm should address any underlying infectious process. The surgical approach is difficult, varies with the condition of the patient, the shape of the aneurysm (saccular or fusiform), and the assessment of bowel viability.

**Infected Aneurysms**

**Mycotic Aneurysms**

The term *myotic aneurysm* is a source of confusion, because there is no association with fungal disease. Although used to describe any infected aneurysm, it should be reserved for infected aneurysms resulting from bacterial endocarditis, as originally described in 1885 by Osler.

Septic emboli from infective endocarditis implant in one of two ways. First, hematogenous seeding of bacteria can occur in non-aneurysmal arteries damaged by preexisting atherosclerosis. Second, septic emboli can become lodged in the vasa vasaorium of larger vessels, causing vessel wall ischemia and infection. In smaller vessels, septic emboli tend to lodge at arterial bifurcations, arteriovenous fistulae, or sites of arterial stenosis. Mycotic aneurysms are most common in the aorta, superior mesenteric artery, intracranial, and femoral arteries.

The infecting organism in mycotic aneurysms reflects the bacteriology of infective endocarditis. *Viridans streptococci* are the most common organisms, although intravenous drug abusers are most often infected by *Staphylococcus aureus*. Patients who have mycotic aneurysms tend to be 30 to 50 years old. The mortality rate is 25% (Table 77.2).

**Atherosclerotic Arteries**

Currently, the most common cause of an infected aneurysm is sepsis with hematogenous spread of bacteria, such as *Salmonella*, *Staphylococcus*, and *Escherichia coli*, to atherosclerotic arteries. Large vessels (especially the aorta) rather than peripheral arteries are the most common site. Patients tend to be older than 50 and have well-established atherosclerosis. Perforation often occurs before diagnosis and carries a mortality rate of 75%.

### Preexisting Aneurysms

The incidence of infection in patients with preexisting atherosclerotic aneurysms is estimated at 3% to 4%, and patients with ruptured aneurysms have a higher incidence of positive bacterial culture results than those who have elective surgical treatment of an asymptomatic aneurysm. Gram-positive organisms, especially *Staphylococcus*, predominate (60%). The rate of mortality is extremely high (90%) because of aneurysm rupture.

### Post-Traumatic Pseudoaneurysms

Post-traumatic infected aneurysms result from invasive hemodynamic monitoring, angiography, and intravenous drug use. The most common artery affected is the femoral because of its involvement in groin injection. *S. aureus* is isolated in 30% to 70% of cases. Because of the more peripheral location and early identification, the mortality rate is low (5%).

The clinical presentation of an infected aneurysm varies with anatomic location and underlying pathophysiologic process. Infected abdominal aneurysms are often misdiagnosed. Onset is usually insidious; low-grade fever may be present for several months. Common findings are fever (75%), back and abdominal pain (33%), and palpable aneurysm (53%). More peripheral aneurysms, especially infected femoral pseudoaneurysms, are characterized by a tender groin mass, some manifestation of sepsis, or bleeding. Almost all are easily palpable. Although rare, fungal infections should be considered in patients who are chronically immunosuppressed, have been treated recently for disseminated fungal disease, or have diabetes mellitus.

Positive blood cultures in a patient with a preexisting aneurysm should prompt treatment as an infected aneurysm until disproven. Bacteremia often is continuous, and blood cultures are positive in approximately 70% of cases, but negative blood cultures do not rule out this diagnosis. Angiography should be performed when an infected aneurysm is suggested. Indium-111–labeled white blood cells can confirm or rule out infected aneurysms.

Treatment includes both antibiotics and surgical repair. Antibiotic therapy is usually continued for at least 6 to 8 weeks, although some physicians advocate lifelong treatment after successful surgical repair. The most important intervention is timely repair. Without surgery, aneurysm rupture with exsanguinating hemorrhage is inevitable.
Traumatic Aneurysms

Traumatic aneurysm refers to a pseudoaneurysm that follows perforation of the arterial wall, with formation of a perivascular hematoma. Chronic traumatic aneurysms may or may not be associated with an arteriovenous fistula. Pseudoaneurysm is a synonym for false aneurysm.

The usual presentation is a pulsatile mass found near the course of an extremity artery, with a history of trauma more than 1 month earlier. The expanding aneurysm may compress associated peripheral nerves. Distal perfusion is usually well maintained, and thromboembolism is rare. A loud systolic and possibly a separate diastolic murmur are characteristic.

Conventional angiography, digital subtraction arteriography, or CT confirms diagnosis. Surgical excision is indicated as currently unknown.

Primary erythromelalgia is a rare syndrome of paroxysmal vasodilation with burning pain, increased skin temperature, and redness of the feet and less often the hands. Secondary erythromelalgia can occur with underlying disease processes, most often systemic lupus erythematous, myeloproliferative disorders, hypertension, venous insufficiency, or diabetes mellitus. Erythromelalgia is as common in children as adults, but in children it is less likely to be associated with underlying systemic illness. Attacks are not triggered by cold and occur in moderate environmental temperatures. Skin temperature of the involved digits is high compared with the patient’s core temperature. Symptoms may remain mild for years or may become disabling. Tissue loss and trophic skin changes do not occur. Although elevation of the extremities, cold compresses or immersion in ice can provide temporary relief, no consistently effective treatment has been found for the multiple, often daily episodes of pain that occur.

THORACIC OUTLET SYNDROME

Thoracic outlet syndrome involves compression of the brachial plexus, subclavian vein, or subclavian artery at the superior aperture of the thorax. Thoracic outlet syndromes were previously categorized by cause as scalenus anticus, costoclavicular, hyperabduction, cervical rib, and first thoracic rib syndromes. They are now most easily divided into three types—neurologic, venous, and arterial—depending on the predominant symptoms.

Compression of the brachial plexus causes the neurologic type of thoracic outlet syndrome and accounts for approximately 95% of all cases. Symptoms begin between the ages of 20 and 50 years old, with women predominating at a ratio of about 3:1. Compression or thrombosis of the subclavian vein constitutes the venous type of thoracic outlet syndrome and is responsible for 4% of all cases. It occurs most often in men 20 to 35 years old. The arterial type of thoracic outlet syndrome is rare, occurring in approximately 1% of all cases, but is potentially the most serious of the three types. Men and women are equally affected in a bimodal age distribution of young adults (from cervical rib compression) and patients older than age 50 (from localized atherosclerosis caused by arterial compression). Figure 77.3 demonstrates the relationship between anatomic abnormalities and neurovascular compression.

Principles

Roos has described four basic concepts of thoracic outlet syndromes: (1) patients who have a thoracic outlet syndrome develop an anatomic abnormality predisposing them to symptoms under certain conditions; (2) brachial plexus compression or irritation constitutes approximately 95% of all thoracic outlet syndrome cases and is rarely caused by compression of the subclavian artery; (3) bedside testing for thoracic outlet syndrome based on positional compression of the subclavian artery is insensitive and unreliable; and (4) in advanced or refractory cases, the causative anatomic abnormalities are to be surgically corrected.

The subclavian artery courses over the first rib between the scalenus anticus muscle anteriorly and the scalenus medius muscle posteriorly, when passing under the clavicle to the axilla, where the brachial plexus lies posteriorly and laterally. Four anatomic abnormalities have been associated with thoracic outlet syndrome.
Clinical Features

Compression of the brachial plexus most often affects the lower two nerve roots, eighth cervical (C8) and first thoracic (T1), producing pain and paresthesias in the ulnar nerve distribution. The second most common pattern is the upper three nerve roots of the brachial plexus (C5, C6, and C7), with symptoms referable to the neck, ear, upper chest, upper back, and outer arm in the radial nerve distribution. Venous compression progresses to intimal damage and subclavian vein thrombosis, with venous engorgement and swelling of the affected extremity. Persistent
subclavian artery compression results in poststenotic aneurysm formation and its sequelae.

Physical Examination

The Adson, costoclavicular, and hyperabduction maneuvers are unreliable as diagnostic tests. The most reliable test in screening for thoracic outlet syndrome is the elevated arm stress test (EAST). With the patient sitting, the arms are abducted 90 degrees from the thorax and the elbows flexed 90 degrees, with the shoulders braced slightly behind the frontal plane. The patient is asked to open and close the fists slowly but steadily for a full 3 minutes and to describe any symptoms that develop. Normal patients perform this test without symptoms other than mild fatigue. The patient with thoracic outlet syndrome usually has early heaviness and fatigue of the involved limb, gradual onset of numbness of the hand, and progressive aching through the arm and top of the shoulder. Within the 3 minutes, the patient usually drops the hand to the lap for relief of the progressive, crescendo distress that becomes intolerable. Patients with carpal tunnel syndrome experience dyesthesias in the fingers but do not have shoulder or arm pain. Patients with cervical disk syndromes have pain in the neck and shoulder but no arm or hand symptoms.

The EAST evaluates all three types of thoracic outlet syndrome: neurologic, venous, and arterial. Radial pulses can be palpated by the examiner during the test. The presence of a radial pulse and a positive EAST test result are strong indications that the basis of symptoms is neurologic involvement of the brachial plexus.

The hands should be observed for changes in skin color, warmth, moisture, or muscular atrophy. Triceps muscle strength (innervated by C7) should be tested bilaterally. Muscle strength of the interosseous muscles (innervated by C8 and T1) should be tested by asking the patient to spread the fingers apart against resistance. The muscles innervated by the radial nerve are tested by having the patient hyperextend the thumb and dorsiflex the wrist against resistance. The median nerve innervates the thenar muscles, which can be tested by asking the patient to abduct the thumb away from the palm with the thumb pointing straight to the ceiling. Tinel's sign ("electric shock" to tips of fingers) is an indication of carpal tunnel compression of the median nerve and is elicited by percussing the volar aspect of the wrist. Gentle pressure with the thumb in the supraclavicular fossa over the brachial plexus may reproduce the thoracic outlet symptoms.

A blood pressure difference between the two arms is a reliable indication of arterial involvement. The blood pressure in the affected arm is lower. Doppler ultrasonography may be helpful in demonstrating comparatively reduced pressure over the pairs of radial, ulnar, and brachial arteries. The supraclavicular area should be auscultated bilaterally for subclavian bruits.

Ancillary Evaluation

Cervical spine radiographs with oblique views and chest radiographs identify skeletal abnormalities (first rib, cervical rib, clavicle deformity), trauma, arthritis, scoliosis, Pancoast tumor, or other pulmonary disease. Electromyography, nerve conduction times, and somatosensory evoked potentials are generally unreliable. Patients thought to have cervical disk or spinal cord disease may require cervical myelography, CT, or MRI.

Arteriography is recommended with (1) obliteration of radial pulse on the EAST, (2) blood pressure 20 mm Hg less than that of the opposite asymptomatic limb, (3) possible subclavian stenosis or aneurysm (bruit or abnormal supraclavicular pulsation), and (4) evidence of peripheral emboli in the upper extremity. Venography is indicated for edema of the hand or arm, unilateral cyanosis, or a prominent venous pattern of the arm, shoulder, or chest.

Differential Diagnosis

The differential diagnosis of thoracic outlet syndrome includes herniated cervical disk, cervical spondylitis, spinal cord tumor, ulnar nerve compression at the elbow, carpal tunnel syndrome, orthopedic shoulder problems, trauma, postural palsy, angina pectoris, and a variety of neuropathies, including those associated with multiple sclerosis, alcoholism, and diabetes.

Patients with a herniated cervical disk have more severe persistent pain radiating in a sharply demarcated dermatomal distribution (usually C4 to C5 or C5 to C6) and often have localized tenderness of the cervical spine at the affected level. Carpal tunnel syndrome is characterized by nocturnal symptoms of pain and paresthesias and an associated Tinel's sign. Brachial plexus compression can be confused with other vascular conditions, such as Raynaud's disease, vasospastic disorders, vasculitis, or arterial ischemia. Unilateral symptoms suggest thoracic outlet syndrome, whereas bilateral symptoms suggest a systemic process. Subclavian or axillary venous thrombosis from thoracic outlet syndrome should be differentiated from thrombophlebitis or mediastinal venous obstruction from a benign or malignant process (Pancoast tumor).

Management

Treatment depends on whether the involvement is neurologic, arterial, or venous. Brachial plexus involvement with minimal signs and symptoms often responds to conservative treatment with physiotherapy and shoulder girdle exercises. Surgery is reserved for patients with intolerable pain or loss of function and strength of the arm or hand. First rib or anomalous muscle or fibrous tissue resection provides consistent relief of symptoms and minimal morbidity (see Fig. 77-4B).

Patients with arterial complications of thoracic outlet syndrome (thrombosis, thromboembolism, or acute ischemia) require immediate heparinization and angiography; Fogarty catheter embolectomy, if appropriate, and emergency or urgent surgical exploration. Patients with axillary and subclavian vein thromboses also require emergent heparinization and venography and are treated with surgical thrombectomy or systemic fibrinolytic therapy.

Disposition

The correct diagnosis of thoracic outlet syndrome can be achieved in more than 90% of patients with a careful history, physical examination, and bedside testing alone. Neurologic, orthopedic, or vascular surgery consultation is indicated according to the pathologic condition.

Peripheral Arteriovenous Fistulæ

Acquired peripheral arteriovenous fistulæ are most often caused by trauma (gunshot wounds, stab wounds, or surgery), with malignancy, infection, and arterial aneurysms as less common causes. Patients seek care months after an invasive surgical procedure or penetrating injury.

Differential Diagnosis

An arteriovenous fistula diagnosis can be made with clinical examination alone. A constant systolic and diastolic (to-and-fro) murmur with associated palpable thrill is characteristic. Sixty percent of arteriovenous fistulæ have a coexisting false aneurysm. Patients with peripheral venous disease may have similar cutaneous manifestations (varicose veins and stasis pigmentation) but lack vascular bruits. Infection may complicate large fistulæ.
Management

Acquired peripheral arteriovenous fistulae usually increase in size with time if surgery is delayed. Vessel dilation, peripheral ischemia, and cardiac output increase. Transcatheter embolization with detachable balloons and liquid acrylic tissue adhesives (eg, isobutyl 2-cyanoacrylate) is used for surgically inaccessible fistulae.

VASCULAR ABNORMALITY CAUSED BY DRUG ABUSE

Principles

Parenteral drug use causes intravenous or intra-arterial injuries, including arterial ischemia, infected pseudoaneurysms, lymphatic obstruction, or neurologic injury.

Acute arterial ischemia results from direct drug effects or endogenous catecholamine release after injection. Endothelial wall damage stimulates platelet aggregation and thrombus formation. Precipitated crystals, talc, or foreign body emboli cause arterial occlusion. Necrotizing arteritis produces ischemia, especially in patients who abuse methamphetamines.

Infected pseudoaneurysms associated with arteriovenous fistulae result from a through-and-through puncture of the artery with simultaneous bacterial contamination. These fistulae are the most common vascular lesions resulting from intravenous drug abuse. Secondary infection of the vascular structure may be covered by a surrounding soft tissue infection (cellulitis or abscess). Infected aneurysms at sites distant from the injection can occur.

Intravenous drug abusers can develop unilateral hand edema or “puffy hand syndrome” due to gradual obliteration of the superficial venous vessels and chronic lymphatic obstruction. Direct injury to adjacent nerves, polyneuritis, and ischemic neuromuscular deficits may accompany this syndrome. Necrotizing arteritis produces ischemia, especially in patients who abuse methamphetamine.

Clinical Features

Patients withhold information about the use of intravenous drugs, but objective evidence such as track marks may be present. Distal ischemia after intra-arterial injection occurs in the upper extremity but objective evidence such as track marks may be present. Distal ischemia. Ultrasonography is often unable to distinguish an aneurysm from an abscess or cellulitis.

Management

Therapeutic considerations for acute ischemia from intra-arterial injection are primarily conservative. Intra-arterial vasodilators, heparin, low-molecular-weight dextran, fibrinolytic therapy, analgesics, systemic warming to stimulate vasodilation, antibiotics, elevation of the affected limb to promote venous drainage, and physical therapy have not significantly altered the outcome or amputation rate in this patient population. Surgical treatment is reserved for delayed amputation. Gradual resolution without surgical intervention is the most common outcome.

Patients with infected pseudoaneurysms require aneurysm resection, débridement of infected tissue, and ligation of the proximal and distal uninfected arteries. Autogenous vein bypass through uninfected tissue planes may require an extensive surgical approach. Intra-arterial nafcillin is recommended for mild infections, nafcillin and a second- or third-generation cephalosporin for major infections, and vancomycin and a second- or third-generation cephalosporin or an aminoglycoside for patients who are bacteremic or overtly septic. Methicillin-resistant S. aureus and gram-negative rods are increasing in frequency as the causative agents, and vancomycin should be added if these organisms are suspected.

KEY CONCEPTS

- Acute arterial occlusion is a limb-threatening emergency requiring early heparinization and Fogarty catheter embolectomy. The clinical diagnosis is based on some variant of the five Ps: pain, pallor, pulselessness, paresthesias, and paralysis. Confirmatory tests are unnecessary and increase the limb’s ischemic status.
- Atheroembolism (blue toe syndrome) is associated with cool, painful cyanotic toes in the presence of palpable distal pulses. A proximal source should be localized, most often an atherosclerotic aneurysm in the aorta or the iliac, femoral, or popliteal artery.
- Popliteal aneurysms are bilateral in 60% of patients and often coexist with an abdominal aortic aneurysm.
- The classic Raynaud attack is triphasic: the fingers become white, blue, and then red. Raynaud’s disease has no detectable underlying cause and usually has a benign course. Raynaud’s phenomenon has an underlying disorder, usually connective tissue disease.
- The only reliable clinical test for detection of thoracic outlet syndrome is the elevated arm stress test (EAST).
- Partial arterial lacerations continue to bleed, resulting in an expanding hematoma. Complete arterial transections initially have only moderate bleeding but can result in delayed hemorrhage. Blunt arterial injury may produce intimal disruption resulting in dissection, thrombosis, and/or obstruction. Arterial vasospasm can accompany injuries adjacent to the blood vessel but spontaneous resolution always occurs in the absence of arterial disruption or intimal injury.
- Aneurysms and arterial stenoses are characterized by a systolic murmur. Pseudoaneurysms, associated with prior surgical or trauma sites, are characterized by a loud systolic and possibly a separate, faint diastolic murmur. Arteriovenous fistulae are characterized by a harsh “to and fro” murmur associated with a palpable thrill.
- Intra-arterial injection of illicit drugs into the brachial or radial artery is associated with immediate onset of a severe, burning pain, and emergency department presentation with patchy blue-purple skin discoloration. Because patients tend to seek attention early and may withhold information about the use of intravenous drugs, identifying the site of injection is helpful in confirming this syndrome, which can be associated with persistent ischemia and tissue loss.
77.2. What is the most frequent site of acute arterial embolic occlusion?

A. Carotid artery
B. Common femoral artery
C. Mesenteric artery

Answer: C.

83.6. A 63-year-old male presents with acute onset of left leg pain while walking. He describes it as a shock-like sensation that made his knee buckle. Past history is remarkable for hypertension, diabetes (diet controlled), tobacco use, and a recent lateral wall myocardial infarction. Current medications are aspirin, metoprolol, and lisinopril. Vital signs are: temperature, 37.0°C oral; heart rate, 98 beats per minute; blood pressure, 1050.e1
160/105 mm Hg; respiratory rate, 20 breaths per minute; and oxygen (O₂) saturation, 96%. Physical examination is remarkable for left lower extremity pallor with decreased light touch sensation, nonpalpable left foot pulses, and minimal capillary refill. What would be the most appropriate next step in the diagnosis and management of this patient?

A. Abdominal ultrasonography
B. Arteriogram
C. Serum lactate level
D. Thoracolumbar magnetic resonance imaging (MRI) scan
E. Vascular surgery consultation

**Answer:** E. This patient has acute limb ischemia from an acute arterial embolus, most likely originating from his left ventricle secondary to a recent myocardial infarction. Loss of light touch sensation on physical examination indicates jeopardized tissue viability, requiring immediate vascular surgery consultation for emergent Fogarty catheter embolectomy. Reliable diagnosis of an acute arterial embolism can almost always be made by history and physical examination alone. Any additional diagnostic evaluation constitutes an unnecessary delay. Serum lactate level, abdominal ultrasonography, and thoracolumbar magnetic resonance imaging (MRI) scan would not provide useful information. An arteriogram before going to the operating room is an unnecessary delay and may further exacerbate limb ischemia.

77.4. A supine patient is asked to raise his foot 12 inches above the estimated level of the right atrium and dorsiflex the foot five or six times. He is then brought to a sitting position with his feet hanging. In the absence of severe advanced ischemia, venous filling of the foot should return in less than how many seconds?

A. 1
B. 5
C. 10
D. 15
E. 20

**Answer:** E. This bedside test is Buerger’s sign and can provide reliable evidence of advanced ischemia. In the absence of severe advanced ischemia, the lower extremity veins should fill within 20 seconds after being placed in the dependent position.

77.5. A 73-year-old man presents with acute onset of right lower extremity pain. He has a long history of tobacco use, hypertension, and a several year history of moderate calf claudication at 50 yards walking. Physical examination reveals signs of chronic atherosclerotic occlusive disease of the bilateral lower extremities, including muscular atrophy, loss of hair over the toes and feet, and thickening of the toenails. Examination of the distal right lower extremity reveals pallor, absent popliteal and foot pulses, and decreased sensation to light touch of the right foot. The cardiac examination is unremarkable, and the 12-lead electrocardiogram (ECG) reveals only normal sinus rhythm. Based on the most likely diagnosis, what is the most appropriate definitive therapy?

A. Acute hyperbaric oxygen therapy
B. Arteriogram to determine the presence of embolus versus in situ thrombosis
C. Intra-arterial thrombolysis
D. Surgical referral for Fogarty catheter embolectomy
E. Surgical referral for Fogarty catheter embolectomy with vascular bypass grafting

**Answer:** E. This patient has a history and physical examination consistent with long-standing peripheral atherosclerotic occlusive disease, no evidence of a proximal source for embolism, but acute onset of ischemic symptoms and loss of light touch in the affected extremity. The most likely diagnosis is a large, in-situ thrombosis precipitating acute limb-threatening ischemia. When limb-threatening ischemia is present, emergent surgical referral for Fogarty catheter embolectomy is indicated, whether caused by acute in-situ thrombosis or embolus. With limb-threatening ischemia caused by in-situ thrombosis, simple Fogarty catheter embolectomy is insufficient and usually requires additional bypass grafting. Acute hyperbaric oxygen therapy has no role in the treatment of limb-threatening ischemia due to in-situ thrombosis or embolism. An arteriogram to determine the presence of embolus versus in-situ thrombosis is unwarranted, represents an unnecessary delay, and may further exacerbate ischemia. Intra-arterial thrombolysis takes 6 to 72 hours to work and is contraindicated in cases of limb-threatening ischemia.

77.6. What percentage of patients presenting with arteriosclerosis obliterans are younger than 50 years old?

A. 1%
B. 5%
C. 10%
D. 20%
E. 40%

**Answer:** D. Peripheral arteriovascular disease can occur in younger patients. Nineteen percent of patients presenting with atherosclerosis obliterans are between the ages of 30 and 50 years old. Of all arteriosclerosis patients, 33% have coexistent coronary artery disease, and 70% to 90% are smokers. The non-smokers have other risk factors including significant hypertension and hyperlipidemia.

77.7. A 49-year-old woman presents with severe left ankle pain. She describes fairly sudden development of a left lateral malleolus hemorrhagic blister that transitioned to a painful superficial ulcer over 48 hours. She has no prior history of extremity ulcers, and her only significant past medical history is hypertension. She has a long-standing history of noncompliance with her hypertensive medications and smokes two packs of cigarettes per day. She has no history of myalgias, joint pain, fever, or systemic symptoms. Vital signs are: temperature, 36°C oral; heart rate, 90 beats per minute; blood pressure, 210/125 mm Hg; respiratory rate, 20 breaths per minute; and O₂ saturation, 96%. Physical examination reveals a thin black female in distress because of pain. Cardiopulmonary examination is unremarkable. Abdominal, neurologic, and extremity examinations are likewise unremarkable except for a well-demarcated, shallow 4 × 3 cm ulcer over the left lateral malleolus. There is mild erythema but no evidence of active infection. Distal pulses and capillary refill are normal. What would be the most appropriate intervention?

A. Analgesics and admission for vasculitis evaluation
B. Surgical consultation for possible embolectomy
C. Wound care and blood pressure control
D. Wound care and tapering dose of prednisone
E. Venous Doppler scans and surgical consultation for possible skin grafting

**Answer:** C. This patient has a hypertensive ulcer, which is the most painful of lower extremity ulcers. They typically occur over the lateral malleolus, as opposed to venous stasis ulcers, which are more common anteriorly and medially. Ischemic arterial ulcers are more common distally over the digits. Although vasculitis or a collagen vascular disease are possible, the lack of any other systemic symptoms or prodrome argue against this.
CHAPTER 78

Pulmonary Embolism and Deep Vein Thrombosis

Jeffrey A. Kline

PRINCIPLES

This chapter discusses the diagnosis and treatment of venous thromboembolism (VTE), including deep vein thrombosis (DVT) and pulmonary embolism (PE), from the perspective of the emergency clinician and provides a resource for the diagnostic consideration and treatment of VTE in the emergency department (ED).

Anatomy and Pathophysiology of Thrombosis

As illustrated in Fig. 78.1, blood clots form when fibrinogen synthesis and promote its catalysis to fibrin include systemic inflammation, traumatic or immune-related vascular trauma, inherited thrombophilias and hemoglobinopathies, cancer, pregnancy, and sluggish blood flow. The triad of venous injury, slow blood flow, and hypercoagulability are the cardinal inciting mechanisms for VTE, and most clinical decision rules for VTE incorporate these factors. Additionally, each year of life independently increases the likelihood of imbalanced clot formation. Clot formation can be accelerated by impaired fibrinolysis, as occurs in pregnancy, and sluggish blood flow. The triad of venous injury, slow blood flow, and hypercoagulability are the cardinal inciting mechanisms for VTE, and most clinical decision rules for VTE incorporate these factors. Additionally, each year of life independently increases the likelihood of imbalanced clot formation. Clot formation can be accelerated by impaired fibrinolysis, as occurs in the metabolic syndrome, and from smoking.

DVT represents a disease spectrum ranging from a minimally symptomatic isolated calf vein thrombosis to a limb-threatening iliofemoral venous obstruction, causing the condition known as phlegmasia cerulea dolens (Fig. 78.2). In 2011, the Healthcare Cost and Utilization Project (HCUP) Nationwide Emergency Department Sample (NEDS) had demonstrated that US emergency clinicians diagnose lower extremity DVT in approximately 170,000 patients, or approximately 1 in every 500 adult ED patients.1

The venous anatomy of the lower extremity is divided into the deep and superficial systems (Fig. 78.3). The superficial venous system consists primarily of the greater and short saphenous veins and perforating veins. The deep venous system includes the anterior tibial, posterior tibial, and peroneal veins, collectively called the calf veins. The calf veins join together at the knee to form the popliteal vein, which extends proximally and becomes the femoral vein at the adductor canal. The femoral vein was previously named the superficial femoral vein but, because this nomenclature caused dangerous confusion, its use has been abandoned in favor of femoral vein. The femoral vein is joined by the deep femoral vein and then the greater saphenous vein to form the common femoral vein, which subsequently becomes the external iliac vein at the inguinal ligament. Proximal DVT refers to a clot in the popliteal vein or higher, whereas distal clot refers to an isolated calf vein thrombosis. Distal greater saphenous vein clots are sometimes denoted as superficial thrombosis, but greater saphenous clots near its connection with the femoral vein should be referred to and treated as proximal DVT.2 Knowledge of venous anatomy helps practitioners understand the difference in venous ultrasound examinations. A two-point venous ultrasound includes the common femoral and popliteal vein. A three-point ultrasound includes the common femoral, femoral, and popliteal veins. A whole-leg ultrasound includes a three-point ultrasound and the peroneal and tibial calf veins.

Clinical Features

Hallmarks of DVT include unilateral limb pain and swelling. Often, DVT produces initially subtle and nonspecific symptoms, such as a mild cramping sensation or sense of fullness in the calf, without objective swelling on examination. Many patients use the term Charley horse to describe the sensation of an early DVT. Because the left iliac vein is vulnerable to compression by the left iliac artery (May-Thurner syndrome), leg DVT occurs with a slightly higher frequency in the left leg compared with the right; bilateral leg DVT is found in fewer than 10% of ED patients diagnosed with DVT. Similarly, the clinical signs of DVT vary and may include edema, erythema, and warmth of the affected extremity, tenderness to palpation along the distribution of the deep venous system, dilation of superficial collateral veins, and a palpable venous cord. Fever suggests an alternative diagnosis, such as cellulitis. Upper extremity DVT is, by definition, a thrombosis in the axillary vein, whereas thrombosis of the brachial vein is a superficial thrombosis. Usually, upper extremity DVT presents with arm swelling, on the same side as an indwelling catheter or recent intravenous infusion. In the absence of a catheter, the most frequent location of arm DVT is on the dominant hand side, and patients may present with a subtle complaint, such as noting that their rings have become tight. Other sites of venous thrombosis occasionally encountered in the ED include the jugular, ovarian, mesenteric, renal, portal, hepatic, cerebral, and retinal veins. These are considered unusual sites for venous thrombosis.

DIAGNOSIS

Diagnosis of DVT and PE starts with an estimation of the pretest probability (PTP). This estimation may be accomplished by the clinical gestalt of an experienced practitioner or in conjunction with a clinical decision tool, such as that derived and validated by Wells and colleagues (Table 78.1). PTP for DVT can also be assessed by gestalt or an unstructured method with equal accuracy, although Wells’s score may be preferred because it has been tested in larger numbers.3 One PTP score has been derived and initially validated for pregnant patients, the LEFT score: 1 point in case of left (L) leg suspicion, 1 point for edema (E), and 1 point if the suspicion occurred during the first trimester (F) of pregnancy, with a score of 0 or 1 tantamount to a low PTP.4 The PTP dictates the pathway for diagnostic testing (Fig. 78.4). The Wells and unstructured (gestalt) methods have approximately equal
overall diagnostic accuracy. Either method is acceptable. Although only performed 50% of the time, all patients should have a PTP assessed and documented prior to additional testing for DVT or PE. For all practical purposes, the diagnosis of DVT is confirmed by a positive compression ultrasound.

**Differential Diagnosis**

Venous insufficiency that causes venous hypertension and inflammation with pain is the most common alternative diagnosis to acute DVT, producing many of the same findings (Table 78.2). Cellulitis is probably the second most common alternative. However, in a patient with clinical evidence of cellulitis, the frequency of concurrent DVT is approximately 3%, suggesting that the diagnostic evaluation for DVT in cellulitis patients should be restricted to those with a high PTP. Other conditions that mimic DVT include muscle strain, hematoma, Baker’s cyst, and lymphedema.

Diagnostic Testing

Laboratory Evaluation

A normal quantitative D-dimer concentration in a patient with a low PTP can be used to exclude proximal DVT (diagnostic sensitivity $\approx 95\%$; specificity $\approx 50\%$). The D-dimer results from the enzymatic breakdown of cross-linked fibrin in any intravascular thrombus. Many conditions elevate the D-dimer other than DVT and PE. The US Food and Drug Administration (FDA) has cleared numerous D-dimer assays, and many use varying threshold cutoffs for abnormal. Most D-dimer assays that have FDA clearance to aid in the diagnosis and exclusion of VTE have a cutoff value of 500 ng/mL. Numerous clinical laboratories, however, use D-dimer assays that do have this specific indication, and many of these assays have cutoffs other than 500 ng/mL.

Radiographic Evaluation

Venous duplex ultrasonography, performed by a certified sonographer and interpreted by a board-certified radiologist or similarly credentialed expert, has a sensitivity and specificity of approximately 95%, respectively, for proximal DVT and is the diagnostic test of choice in most centers. A patient at a low PTP may have the diagnosis of DVT effectively excluded by a negative
three-point venous duplex ultrasound, which images the common femoral, femoral, and popliteal veins (see Fig. 78.2). However, for patients at higher than low risk, a single negative three-point ultrasound is inadequate as a sole method to exclude DVT, whereas a single normal whole-leg ultrasound (including normal calf and saphenous veins) is sufficient to exclude DVT with any PTP. A negative three-point ultrasound, together with a negative quantitative D-dimer, excludes DVT with any PTP. If a patient with a moderate to high PTP and elevated D-dimer level (or not performed), a negative three-point ultrasound at the index visit should be followed by a repeat ultrasound in 2 to 7 days. If negative, this is sufficient to exclude DVT, and ostensibly, PE. An expertly performed and interpreted positive ultrasound is sufficient to confirm the diagnosis of DVT. Ultrasound cannot be used to rule out iliac or pelvic vein thrombosis. When duplex ultrasound is not available, patients with a moderate to high PTP should receive empirical low-molecular-weight (LMW) heparin while awaiting the availability of ultrasound imaging, whereas patients with a low or moderate to high PTP with a negative D-dimer do not need empirical anticoagulation while they wait for diagnostic imaging. Aggregated data have now demonstrated that emergency clinician–performed three-point ultrasound for lower extremity DVT has adequate diagnostic accuracy (96% sensitivity, 96% specificity) to diagnose and exclude DVT in the hands of an experienced ultrasonographer. Magnetic resonance imaging (MRI) can evaluate the pelvic vasculature and vena cava, which is not possible with ultrasound. MRI does not produce ionizing radiation. Thus, MRI is a logical option to evaluate the pelvic veins of patients at high risk for pelvic vein thrombosis (eg, those with gynecologic malignancy) and for pregnant patients. Its use is limited by cost, availability, patient size, and tolerance to close quarters. MRI is not the primary diagnostic test for patients with suspected DVT.

**Management**

For patients with high PTP after hours, and for patients with a positive ultrasound, anticoagulation should be initiated emergently, unless contraindicated, as outlined in Table 78.3. Most patients with DVT can be treated at home, assuming that the patient can effectively adhere to the chosen anticoagulation strategy. The antiquated concept that patients with DVT should be at bed rest is categorically incorrect, and patients should be encouraged to ambulate after anticoagulation for DVT to reduce the incidence of postthrombotic syndrome. Note that the presence of a so-called free-floating DVT does not increase risk of embolization. Compression stockings can no longer be advocated routinely for DVT, although patients with persistent swelling or superficial thrombosis may benefit.

**Superficial Leg Thrombophlebitis**

Based on the results of a large randomized controlled trial, patients with a clot in the greater saphenous vein that extends above the knee are at risk for progression to DVT via the saphenous-femoral vein junction and may require an abbreviated course of anticoagulation. Published evidence has suggested that distal saphenous vein thrombophlebitis can adequately be treated with nonsteroidal antiinflammatory drugs, heat, and graded compression stockings (fitted to exert 30–40 mm Hg of pressure at the ankle), followed by a scheduled repeat ultrasound in 2 to 5 days. If a greater saphenous vein clot is proximal, near the connection with the femoral vein (see Fig. 78.3), anticoagulation is indicated. The precise duration of anticoagulation treatment remains uncertain, but we recommend full-dose LMW heparin or fondaparinux for 10 days followed by a repeat ultrasound. If the repeat ultrasound shows improvement, anticoagulants can be discontinued.

**Isolated Calf Vein Thrombosis**

The optimal management strategy for thromboses of the tibial or peroneal veins remains controversial, although it is clear that anticoagulation lowers the rate of proximal propagation and embolization. For tibial or peroneal vein thrombosis in an otherwise healthy ambulatory patient, with no other indications for anticoagulation, the recommendation is short-term anticoagulation, most easily accomplished with rivaroxaban (15 mg bid for 14 days then 20 mg QD) or apixaban (10 mg bid for 7 days, then 5 mg bid for 7 days), or antiplatelet therapy with aspirin (325 mg/day of enteric-coated acetylsalicylic acid) and close follow-up with repeat duplex ultrasound scan at 2 to 5 days to evaluate for clot propagation.

**Phlegmasia Cerulea Dolens (Painful Blue Leg)**

Massive iliofemoral vein occlusion results in swelling of the entire leg, with extensive vascular congestion and associated venous ischemia, producing a painful cyanotic extremity. There may be an associated arterial spasm resulting in phlegmasia alba dolens (painful white leg or so-called milk leg), which may mimic an acute arterial occlusion. Prompt consultation with a vascular surgeon should be obtained because patients with phlegmasia cerulea dolens may require emergent thrombectomy. If timely consultation is not possible, early thrombolytic therapy may be a limb-salvaging procedure in the absence of contraindications. One strategy is to infuse alteplase via an infusion catheter placed into the thrombus. This procedure requires interventional radiology capabilities, and therefore emergency clinicians caring for patients with evidence of phlegmasia cerulea dolens in hospitals

*Although low-molecular-weight heparin compounds are usually injected subcutaneously, no trials have been conducted to justify this route over intravenous injection. Intravenous injection achieves more rapid anticoagulation and does not produce more bleeding."
without the resources immediately available should not delay transfer to an interventional radiology–capable center.

Upper Extremity Venous Thromboses

DVTs of the upper extremity have become more common in association with the increased use of indwelling venous catheters and wires for electronic cardiac devices. Upper extremity DVT can cause PE, and all patients with DVT above the elbow require definitive treatment. About half of all upper extremity DVTs are associated with an indwelling catheter, and peripherally inserted central catheters (PICCs) carry the highest risk. Aggregated data have indicated that only venous ultrasound has been adequately validated as a method to diagnose and exclude upper extremity DVT, and D-dimer has only been examined in one study. In the absence of pain or infection, catheter-associated DVT does not automatically warrant catheter removal if the catheter serves a current and vital purpose. However, these patients should receive anticoagulation absent contraindications. The duration of recommended anticoagulation following catheter removal for DVT remains variable, but most published guidelines recommend at least 3 months. Acute PE from an axillary vein occurs in about 9% of patients with arm DVT, although the PE tends to be less severe from upper extremity DVT. Isolated upper extremity DVT, especially axillary-subclavian vein thrombosis, also can be seen in relatively young, active, otherwise healthy patients after considerable exertion of the dominant arm, known as effort DVT, or Paget-Schroetter syndrome. Optimal treatment of isolated brachial vein thrombosis, often the result of a recent intravenous infusion (so-called infusion phlebitis) also remains uncertain, and no study has demonstrated clear benefit for systemic anticoagulation. I recommend the same management plan as described for superficial thrombophlebitis of the leg.

Complications

Although the most feared complication of DVT is fatal PE, DVT damages venous valves, causing venous insufficiency. Venous insufficiency, in turn, manifests as a spectrum ranging from painless varicosities to severe postthrombotic syndrome, which can cause unremitting pain and swelling, varicose veins, skin changes, and nonhealing ulcers in 5% to 10% of patients. Fig. 78.5 shows the leg of a construction worker with a femoral DVT that produced moderate postthrombotic syndrome, resulting in swelling on the job, impairing his ability to work. Compression stockings reduced the swelling and provided some improvement.

Disposition

Assuming that systemic anticoagulation can be reliably established, most patients with acute DVT can be discharged from the ED. Protocols that use monotherapy such as apixaban or rivaroxaban can facilitate this process. I recommend selecting patients for home therapy using the modified Hestia criteria (Box 78.1).

PULMONARY EMBOLISM

Principles

A PE results when a clot that formed hours, days, or sometimes weeks earlier in the deep veins dislodges, travels through the venous system, and traverses the right ventricle into the pulmonary vasculature.

Pathophysiology of Pulmonary Vascular Occlusion

The right ventricle normally pumps through a pulmonary vascular tree with a low resistance to fluid flow, and young persons without cardiopulmonary disease (eg, congestive heart failure, chronic obstructive lung disease, advanced sarcoidosis, pulmonary fibrosis, scleroderma, primary pulmonary hypertension) can tolerate at least 30% obstruction from a clot, with minimal symptoms or signs. Pulmonary infarction, in contrast, can produce severe pleuritic pain. Although a segmental pulmonary artery constitutes only about 1/6 of the entire pulmonary vascular circuit, a clot lodged deeply in a segmental artery can obstruct blood flow to a sufficient degree to cause tissue necrosis. Table 78.4 presents a listing of factors that significantly increase the probability of PE in the ED population. Not all variables that increase the probability of PE in epidemiologic studies also increase the probability of a PE diagnosis in individual ED patients with signs and symptoms suggesting PE. From an epidemiologic standpoint, people who smoke have a significantly higher risk for venous clots than people who do not smoke. However, in the ED, smoking does not seem to increase that person’s risk for PE over that of a nonsmoker with an otherwise identical clinical presentation. It is possible that smokers are simply more likely to have other lung problems that manifest a clinical presentation similar to that of PE. As many as 50% of patients diagnosed with PE have no apparent clinical risk factors for VTE, but testing for genetic

**Modified Hestia Criteria to Select Patients With Deep Vein Thrombosis and/or Pulmonary Embolism for Outpatient Treatment**

Identifies low-risk PE if:
- Systolic blood pressure > 100 mm Hg
- No thrombolysis needed
- No active bleeding
- Oxygen required to maintain oxygen saturation > 94%
- Not already anticoagulated
- Abundance of severe pain requiring > two doses of intravenous narcotics
- Other medical or social reasons to admit
- Creatinine clearance > 30mL/min
- Not pregnant, severe liver disease, or heparin-induced thrombocytopenia

- Pulse oximetry reading < 95% (sea level): V/Q mismatch, +++
- Unilateral leg or arm swelling: Venous obstruction, ++++
- Normalization of vital signs: Presumptive from treatment or Hawthorne effect, Not significant

*DVT, Deep vein thrombosis; PE, pulmonary embolism; V/Q, ventilation–perfusion ratio.*

thrombophilia has no value in the ED setting, or any other setting.28

**Clinical Features**

Symptoms vary widely during this process, ranging from no symptom to cardiovascular collapse. The patient can feel focal, sharp, pleuritic pain and exhibit a splinting response to breathing. Over several days, the infarcted segment becomes consolidated on chest radiography and exudes a pleural effusion, manifesting an intense underlying inflammatory process. Chest pain from non-infarcting PE can be highly variable and vague, with as many as 30% of patients with definite PE having no perception of chest pain.29

In contrast, if asked in a detailed and structured way, approximately 80% of patients with PE admit to having some sensation of dyspnea.29 The dyspnea may be constant and oppressive or may be intermittent and perceived only with exertion, possibly due to an exercise-induced increase in pulmonary vascular resistance.

Pulmonary embolism can produce hypoxemia (pulse oximetry reading <95% at sea level or <92% in Denver or Salt Lake City), but the degree of hypoxemia is unpredictable. Approximately half of all patients with PE have no evidence of hypoxemia. A swine model mimicking massive pulmonary vascular occlusion (increase in systolic pulmonary arterial pressure to ≈65 mm Hg) did not show any decrease in pulse oximetry reading (from 98% preembolization to 98% postembolization).30 Despite its shortcomings as a single diagnostic step, the presence of hypoxemia (pulse oximetry <95%, breathing room air) that cannot be explained by a known disease process increases the probability of PE. Conversely, a normal oxygen saturation, although reassuring, cannot rule out PE. When PE is diagnosed, the severity of hypoxemia represents a significant independent predictor of patient outcome.

PE also causes highly variable effects on other vital signs. In the ED, about half of all patients with PE have a heart rate greater than 100 beats/min.27 Tachycardia from PE probably results from impaired left ventricular filling, leading to a pathophysiologic process that parallels that of hemorrhagic shock. Only about half
of patients have an elevated respiratory rate (>20 breaths/minute). The probability of PE was not reduced in patients who normalized any vital sign while in the ED. About half of patients with PE have a dilated right ventricle on echocardiogram obtained in the ED. Arterial hypotension (systolic blood pressure < 90 mm Hg) represents an ominous hemodynamic consequence of PE; it occurs in only about 10% of patients, but signifies a fourfold increase in risk of death compared with normotensive patients. In its most extreme form, PE can obstruct the right ventricular outflow entirely by casting the entire pulmonary vascular tree (Fig. 78.6) or acutely occluding the main pulmonary artery. Pulseless electrical activity (PEA) is the most common electrocardiographic result from obstructive PE. The survival rate from cardiac arrest from PE is about 20%, even if the arrest is witnessed, and treatment with bolus fibrinolysis is initiated.

PE can present as cardiac arrest. Most patients with incipiently fatal PE have overt respiratory distress, syncope or seizure-like activity, or high heart rate relative to the systolic blood pressure before arrest. First responders who observe a patient dying from PE usually observe PEA as the initial cardiac arrest rhythm (>20 depolarizations/minute, without palpable pulses). The mechanism for PEA manifests from right ventricular outflow obstruction and impaired right ventricular contractility. Ultrasound performed during PEA arrest from PE usually shows weak cardiac contractions, with a swollen right ventricle and small left ventricle. Some patients manifest slow agonal rhythms with fatal or near-fatal PE, possibly due to septal wall tension leading to ischemia or an ischemic-equivalent effect on the atrioventricular node and infranodal conducting pathways.

Virtually any ED visit related to weakness, shortness of breath, dizziness or syncope, pain, extremity discomfort, or nonspecific malaise or functional deterioration could represent a potential PE. However, this does not mean that every patient with these symptoms should be evaluated for PE, and these symptoms need to be rationally considered in the context of the entire clinical picture. A patient with PE typically presents with 2 to 3 days of constant or worsening shortness of breath. For many patients, the dyspnea is only present with exertion, and patients often need to be prompted to endorse this symptom. Patients usually describe chest pain with PE in vague terms, unless they have pulmonary infarction. About 20% of ED patients with PE have focal pleuritic chest pain, but many say nonspecifically that their chest hurts with breathing, usually on the lateral aspects. Those with lung infarction can present with a clinical picture similar to that of lobar pneumonia, including focal chest pain, fever, and unilateral rales on auscultation. However, a temperature greater than 101.5°F (38.6°C) suggests infection rather than infarction. On occasion, pulmonary infarction may present with an onset of pain and hemoptysis simultaneously. In contrast, lobar pneumonia, which usually presents with productive cough for a few days before rust-tinted sputum appears. Isolated subternal chest pain is a rare presentation for PE and, in general, suggests a cardiac or other origin.

Most patients with PE have no obvious abnormality on physical examination, other than an affect that gives the appearance of distress or anxiousness, with respiratory distress. The only positive finding from the itemized physical examination that reliably increases the probability of PE is evidence of a DVT—unilateral leg asymmetry, unilateral edema, tenderness along a deep vein. On the other hand, wheezing, or a prolonged expiratory phase on lung auscultation, suggests the alternative diagnosis of bronchospasm, which reduces the probability of PE. Bilateral rales suggest the diagnosis of left ventricular failure, although localized rales often are heard over infarcted lung tissue.

When retrospectively comparing patients in whom the diagnosis of PE was delayed, patients who were admitted to the hospital tended to have a higher frequency of altered mental status, new or at baseline dementia, and more comorbid conditions. Only one recent study has evaluated patients discharged and subsequently diagnosed with PE. Those patients tended to lack fever and had pleuritic chest pain and hemoptysis, together with a pulmonary infiltrate on imaging, lower D-dimer concentration, and small distal clot seen on pulmonary vascular imaging. Thus, patients who were discharged with PE seemed to have isolated pulmonary infarction that was often misidentified as pneumonia. Coincidentally, in a secondary analysis of a large database of PE-positive patients, to which I applied the PERC (pulmonary embolism rule-out criteria) rule (Box 78.2) to understand the profile of the PE-positive but PERC-negative patients better, the presence of pleuritic chest pain emerged as a common feature. It appears as though emergency clinicians may be prone to miss small, distal lung clots that produce a clinical picture of pneumonia. More evidence is needed to determine if these patients, in the absence of DVT, benefit from systemic anticoagulation.

### Differential Diagnosis

Pneumonia is the most common alternative diagnosis found in ED patients, diagnosed in 5% to 10% of scans, and in many studies was a more common finding than PE on computed tomography pulmonary angiography (CTPA). Other similar findings include exacerbations of chronic obstructive pulmonary...
disease, asthma, pulmonary vascular disease, including all causes of pulmonary hypertension, pericarditis, pleurisy, costochondritis, spontaneous pneumothorax, acute coronary syndrome (ACS), and chest wall trauma. Most alternative diagnoses can be ruled out with a thorough history, physical, chest x-ray, electrocardiogram (ECG), cardiac enzyme testing, and echocardiography. When the diagnosis is unclear, consider observation or admission.

**Diagnostic Testing**

Fig. 78.7 illustrates an algorithmic approach to PE exclusion and diagnosis in nonpregnant patients. Chest radiography seldom provides specific information, but is useful to suggest alternative diagnoses, such as pneumonia, congestive heart failure, or pneumothorax. If symptoms have been present for 3 days or more, a pulmonary infarction may be visible on chest x-ray as an apical, pleural-based, wedge-shaped area of infiltrate, producing the so-called Hampton’s hump finding. Unilateral lung oligemia (Westermark’s sign) is a rare radiographic manifestation of a large PE.

Likewise, a 12-lead ECG provides more information about the presence of alternative diagnoses (e.g., pericarditis, cardiac ischemia) than the presence of PE. When PE causes electrocardiographic changes, this is usually a result of acute or subacute pulmonary hypertension. The most common effects of pulmonary hypertension on the ECG are rapid heart rate, symmetric T-wave inversion in the anterior leads (V1–V4), the McGinn-White S1Q3T3 pattern, and incomplete or complete right bundle branch block (Fig. 78.8). Any one of these findings approximately doubles the probability of PE in a symptomatic patient.

In the ED, inability to identify a cause of chest symptoms or specific signs may be an important cue to evaluate the patient for PE. Because as many as 50% of patients diagnosed with PE have no identifiable classic risk factors for thrombosis, the decision to pursue the diagnosis of PE is based on that particular patient’s disease, asthma, pulmonary vascular disease, including all causes of pulmonary hypertension, pericarditis, pleurisy, costochondritis, spontaneous pneumothorax, acute coronary syndrome (ACS), and chest wall trauma. Most alternative diagnoses can be ruled out with a thorough history, physical, chest x-ray, electrocardiogram (ECG), cardiac enzyme testing, and echocardiography. When the diagnosis is unclear, consider observation or admission.

CHAPTER 78  Pulmonary Embolism and Deep Vein Thrombosis

Evaluation for PE begins with an assessment of PTP and patients without symptoms or signs of PE (eg, no chest pain, no shortness of breath, no dyspnea on exertion, normal vital signs, and no recent syncope) should not be tested, even in the presence of risk factors. Moreover, many patients with a risk factor and a symptom or sign of PE can still have PE safely excluded without diagnostic testing. Because the evaluation for PE relies heavily on the PTP, an important question to answer is how to quantify the PTP accurately. Several clinical decision rules have been derived and validated for the risk stratification of patients with possible PE; however, difficulty with spontaneous recall and a preference for gestalt reasoning by clinicians may limit their use in clinical practice.45,47

Although gestalt reasoning and clinical decision rules may provide adequate stratification to guide the evaluation (ie, D-dimer vs. pulmonary vascular imaging), these methods alone do not reproducibly identify the very low-risk population whose PTP lies below the 2% test threshold. To identify the very low-risk group in whom PE could be safely excluded at the bedside, with no diagnostic testing, the PE rule-out criteria (or PERC rule; see Box 78.2) can be used.48 When the physician's unstructured clinical suspicion for PE is low, and each of the eight elements of the rule is satisfied, the PERC rule identifies a very low-risk population among whom no patient has a PTP for PE greater than 2% and obviates further testing in about 20% of ED patients.48

For a patient with a high PTP (by any method), emergency clinicians should order pulmonary vascular imaging and consider initiating anticoagulation in the absence of contraindications.49 Patients with a non–high PTP (simplified revised Geneva score < 5, Wells score < 5, or gestalt PTP < 40%) can have PE excluded with a normal D-dimer concentration, using the cutoff for presentation and should not rely on the presence or absence of epidemiologic risk factors.

In some cases, PE can be excluded with reasonable certainty based on data available at the bedside, gathered only by the medical history and physical examination. Multicenter studies of urban academic EDs have suggested that emergency clinicians currently evaluate approximately 2% of all patients for PE with CTPA.42,43 Each year, more than 16 million patients, or 12% of all patients who present to the ED, have chest pain or dyspnea, and not all require an evaluation for PE. Although numerous cases of PE are likely still missed, overtesting for PE can also be harmful. Specific risks include exposure to the ionizing radiation and IV contrast necessary for CTPA and the risk of a false-positive interpretation, which may occur in as many as 10% of scans read as positive for PE.44 The appropriate use of D-dimer testing decreases the need for imaging in all patients with non–high PTP.

A rational strategy to evaluate a patient for PE should begin with estimation of the PTP for PE. Methods for estimating PTP can be implicit, the clinician’s gestalt best guess, or explicit—use of a scoring system, which is synonymous with a clinical decision rule, or clinical prediction rule to categorize the probability (eg, Well’s score, Geneva criteria, Charlotte rule).45

One approach to the evaluation for PE is to compare the PTP with the test threshold for PE. The test threshold represents the point above which some type of evaluation should be initiated and below which the clinician can justify not starting the evaluation. For PE, the test threshold is from 1% to 5%.46 I recommend that patients with a a PTP less than approximately 2% are more likely to be harmed than benefited by an evaluation and vice versa for patients with a PTP greater than 2%. Thus some patients with symptoms and signs of PE can have PE excluded at the bedside using the combination of PTP and additional explicit criteria. Other patients require additional objective diagnostic testing.

Evaluation for PE begins with an assessment of PTP and patients without symptoms or signs of PE (eg, no chest pain, no shortness of breath, no dyspnea on exertion, normal vital signs, and no recent syncope) should not be tested, even in the presence of risk factors. Moreover, many patients with a risk factor and a symptom or sign of PE can still have PE safely excluded without diagnostic testing. Because the evaluation for PE relies heavily on the PTP, an important question to answer is how to quantify the PTP accurately. Several clinical decision rules have been derived and validated for the risk stratification of patients with possible PE; however, difficulty with spontaneous recall and a preference for gestalt reasoning by clinicians may limit their use in clinical practice. Fortunately, gestalt reasoning appears to be comparable to other validated decision rules.45,47

Although gestalt reasoning and clinical decision rules may provide adequate stratification to guide the evaluation (ie, D-dimer vs. pulmonary vascular imaging), these methods alone do not reproducibly identify the very low-risk population whose PTP lies below the 2% test threshold. To identify the very low-risk group in whom PE could be safely excluded at the bedside, with no diagnostic testing, the PE rule-out criteria (or PERC rule; see Box 78.2) can be used.48 When the physician’s unstructured clinical suspicion for PE is low, and each of the eight elements of the rule is satisfied, the PERC rule identifies a very low-risk population among whom no patient has a PTP for PE greater than 2% and obviates further testing in about 20% of ED patients.48

For a patient with a high PTP (by any method), emergency clinicians should order pulmonary vascular imaging and consider initiating anticoagulation in the absence of contraindications.49 Patients with a non–high PTP (simplified revised Geneva score < 5, Wells score < 5, or gestalt PTP < 40%) can have PE excluded with a normal D-dimer concentration, using the cutoff for
abnormal established by the local laboratory. Additionally, assuming the D-dimer of use has a cutoff for abnormal of 500 ng/mL, PE can be excluded with a D-dimer concentration elevated on the basis of age using the following:

\[ \text{Age} 	imes 10 \text{ ng/mL} \]

Thus, an 80-year-old patient with a PE unlikely or non–high PTP can have PE excluded with a D-dimer concentration less than 800 ng/mL. This strategy maintains a diagnostic sensitivity near 95% but increases the percentage of patients who can have PE excluded without pulmonary vascular imaging. The safety of this strategy has not been tested with D-dimer assays with abnormal thresholds different than 500 ng/mL.

The most common causes of a false-negative D-dimer are very small isolated subsegmental PE and chronic PE. Because the half-life of circulating D-dimer is less than 8 hours, the sensitivity of the D-dimer may decrease if the patient’s symptoms have been present for longer than 3 days. False-negative D-dimer measurements may also be seen with severe lipemia and ongoing warfarin therapy.

When the PTP is high, or the screening D-dimer is positive, pulmonary vascular imaging by CTPA or V/Q scanning is advised. Although CTPA is not perfect, it has multiple advantages over V/Q scanning and usually can confirm or exclude the presence of PE.

Most academic centers now use CTPA as the primary method of evaluating for PE. The diagnostic sensitivity and specificity of a technically adequate CTPA scan, performed on a multidetector row scanner, are both about 90%. A good-quality CTPA scan offers the highest level of diagnostic and exclusionary certainty for acute PE. Technical adequacy requires more than 200 HU of contrast opacification in the main pulmonary artery and absence of motion artifact. Emergency clinicians should consult with the radiologist interpreting the CTPA scan to ensure good-quality images for patients with a negative result but a high PTP. If the radiologist indicates that the scan was significantly compromised, the suggested next step is to perform bilateral lower leg ultrasonography and, if negative, repeat bilateral leg ultrasonography 2 to 7 days later.

Emergency clinicians have observed an increased detection of isolated subsegmental filling defects on chest CT, revealed with more thinly collimated images acquired with multidetector row scanner technology. When two radiologists independently evaluate CTPA, their agreement on the presence of isolated subsegmental filling defects is poor.

CTPA can provide additional information to enhance its usefulness in the ED. Although the scan can be extended to include the leg veins (CT venography), the technical reliability of this technique has been questioned, causing it to be abandoned in most centers. CTPA often provides information about alternative processes that might explain the patient’s symptoms.

The V/Q scintillation scan, introduced in the early 1960s, remains a viable diagnostic option for patients with contraindications to iodinated intravenous contrast and vulnerable kidney function. The accuracy and precision of the V/Q scan were shown in the Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) study, which compared the results of V/Q scanning with the most accurate criterion standard test available at the time, formal pulmonary angiography. Fig. 78.9 shows the results of a high-probability V/Q scan. A high-probability V/Q scan can confirms PE, and a normal V/Q scan (ie, no perfusion defect) excludes PE. A moderate-probability or indeterminate scan is essentially nondiagnostic and requires additional formal pulmonary angiography or CTPA. Patients with a low PTP and a low-probability V/Q scan require additional testing, CTPA or bilateral venous duplex ultrasonography of the legs.

**Fig. 78.9.** Scintillation (99mTc) ventilation–perfusion lung scan images showing high probability of acute pulmonary embolism using criteria defined in the prospective investigation of pulmonary embolism diagnosis (PIOPED). The first and third rows project the perfusion phases of the examination, and the second and fourth rows show the ventilation phases. The black arrowheads point to wedge-shaped defects in the perfusion images. Comparison with the corresponding ventilation view immediately below shows relatively homogeneous scintillation activity in the anatomic segments that lack perfusion. These defects are consistent with the effect of acute pulmonary embolism.

**Pregnant Women**

Fig. 78.10 presents an algorithm to diagnose PE in pregnant patients. It is prudent to explain the diagnostic options to the patient, including the risks and benefits of the various tests, obtain her preferences, and document these stated preferences. The algorithm starts with bilateral lower extremity venous ultrasound. If the bilateral ultrasound is positive, treatment can be started. Otherwise, the next step is determined by PTP assessment. To my knowledge, no PTP rules have been validated in pregnant patients. It is clear that over half of all VTE cases diagnosed in pregnancy occur in the third trimester. Based on available patient level data from pregnant ED patients, high Wells and Geneva scores, the third trimester, or unexplained hypoxemia (SaO₂ < 95% breathing room air at sea level) predict a relatively higher PTP for PE. Most patients with pregnancy selected by emergency clinicians for PE evaluation have a low clinical probability. Specialty groups have acknowledged the lack of evidence regarding a recommended approach to the evaluation of pregnant patients with suspected PE, but all agree that effort should be made to avoid fetal exposure to radiation and iodinated contrast. To minimize radiation exposure, I propose a combined approach, in which negative bilateral lower extremity venous ultrasonography is supported by a negative PERC rule and a threshold-adjusted D-dimer assay. The D-dimer threshold can be adjusted according to the trimester of pregnancy, as follows: first trimester, 750 ng/mL; second trimester, 1000 ng/mL; third trimester, 1250 ng/mL. If the patient is has a non–high PTP, has no high-risk factors, is PERC-negative, the bilateral ultrasound is negative, and the D-dimer is below the trimester-adjusted values, PE can be excluded. Note that this recommendation does not state that the PERC criteria can be used alone in pregnancy.

If the D-dimer is abnormal or the patient fails the PERC criteria, a pulmonary vascular imaging study is warranted. The best choice of pulmonary vascular imaging is controversial and uncertain. Current data indicate that CTPA or V/Q scanning will produce adequate images to exclude and diagnose PE in a pregnant patient. The data used to estimate the risk of fetal
exposure to radiation for CT scanning versus V/Q scanning are highly speculative. Shielding the abdomen with a lead or bismuth-antimony apron during CT scanning may reduce radiation based on phantom modeling.\(^6^4\) When available, tube voltage modulating technology may also serve to lower fetal radiation exposure more than shielding.\(^6^4\) However, if both tests are equally available, I prefer to consult with the radiologist on duty to coordinate a stepwise evaluation of the chest radiograph first and, if normal, to proceed to perfusion-only nuclear lung scanning with a half-dose \(^{99}\)Tc-macroaggregate. Because \(^{99}\)Tc is excreted in the urine, prehydration with 1 L of intravenous saline and insertion of a Foley catheter appears to be a logical but unproven step to reduce fetal exposure to radiation. The risk of this approach is that if the perfusion lung scan is not normal, and CT scanning is ultimately required, the mother and fetus will be exposed to more radiation than if CTPA had been performed first.

**Management**

Fig. 78.11 presents a comprehensive management plan for diagnosed PE relevant to the context of a large, full-service (typically known as a tertiary care) hospital. Pathways similar to this have been adopted by multidisciplinary PE response teams.\(^6^5\) At the left-most side of the algorithm, patients can be discharged to home from the ED. At the right side, patients with a massive PE and no contraindications receive bolus thrombolytic therapy.
Fig. 78.11. Comprehensive treatment algorithm for diagnosed acute pulmonary embolism in a large, full-service hospital. *Denotes a controversial pathway that is not available at many smaller hospitals. Many experts believe that anticoagulation alone provides equivalent outcomes. 1. CTPA, CT pulmonary angiography findings: filling defects in a lobar or more proximal artery, right ventricle (RV) > left ventricle (LV) on CT scan; reflux of contrast into inferior vena cava (IVC) and liver. Abnormal echographic findings include dilated or hypokinetic RV and estimated RV systolic pressure > 40 mm Hg. Elevated biomarkers include brain natriuretic peptide (BNP) level > 90 pg/mL pro-BNP level > 900 pg/mL, or any troponin concentration > 99th percentile for normal, with <10% coefficient of variability (ie, borderline or higher).108,109 2. Unfractionated heparin 80 U/kg and then 16–18 U/kg/h to maintain PT of 2–2.5. 3. See Beam and colleagues.36,4 Contraindications to fibrinolysis: Absolute contraindications: 1. gastrointestinal bleeding within previous 30 days; 2. active hemorrhage in any of the following sites at the time of enrollment—intrapertoneal, retroperitoneal, pulmonary, uterine, bladder, or nose; 3. head trauma causing loss of consciousness within previous 7 days; 4. any history of hemorrhagic stroke; 5. ischemic stroke within the past year; 6. history of intraocular hemorrhage; 7. known or suspected intracranial metastasis; 8. liver failure with prothrombin time abnormal (international normalized ratio [INR] > 1.7); 9. surgery that required opening of the chest cavity, peritoneum, skull, or spinal canal within the previous 14 days; 10. subacute bacterial endocarditis under treatment; 11. pregnancy; 12. large pericardial effusion. Relative contraindications: age > 75 years; dementia; surgery more than 30 days but less than 60 days prior; any prior stroke; symptoms suggesting transient ischemic attack in the past 30 days; any prior gastrointestinal bleeding; concurrent use of a thienopyridine (eg, clopidogrel); INR > 1.7 from warfarin use; any metastatic cancer, tongue bites, recent fracture, recent fall with head strike, history of hemorrhia, nosebleeds, recent dental extraction, or orthopedic surgery. HR, Heart rate; SBP, systolic blood pressure.
Standard Anticoagulation

Patients with a high PTP, no contraindication to anticoagulation, and evidence of hemodynamic instability, including recent syncope, any hypotension, hypoxemia, or clinical evidence of right heart strain (criteria defined in Table 78.4) as more severe moderate PE or high-risk PE) should receive empirical heparin prior to waiting for the results of pulmonary vascular imaging. Patients with a positive imaging for DVT or PE should receive anticoagulation using one of the agents in Table 78.3, administered in the ED as soon as the diagnosis is confirmed. Low-molecular-weight (LMW) heparin is advantageous when compared to unfractionated heparin based on robust meta-analyses that have clearly demonstrated lower rates of major hemorrhage, heparin-induced thrombocytopenia, and VTE, with similar cost. Patients can now be anticoagulated in the ED with apixaban (Eliquis) or rivaroxaban (Xarelto), which are orally available agents that specifically inhibit one enzyme in the clotting pathway. These drugs can be started without prior or concomitant use of heparin, and they provide therapeutic anticoagulation effect as rapidly as subcutaneous LMW heparin (see Table 78.3). By obviating the need for twice-daily subcutaneous injections and blood monitoring, these drugs can facilitate outpatient treatment of DVT and PE.

Patients with a history of heparin-induced thrombocytopenia should receive fondaparinux, argatroban, apixaban, or rivaroxaban. Most hematologists, internists, and obstetricians prefer that pregnant patients with VTE receive twice-daily LMW heparin.

The anticoagulant effect of unfractionated heparin can be almost completely and rapidly reversed with protamine, whereas LMW heparin can only be 50% neutralized with protamine. Protamine has no effect on fondaparinux, rivaroxaban, or apixaban. At present, based on data in healthy volunteers, the best agent to correct coagulopathy from apixaban or rivaroxaban is four-factor activated prothrombin complex (Beriplex P/N or K-Centra, 50 U/kg, IV). No clinical trials have been published to test the effect of these agents on bleeding in people with apixaban or rivaroxaban coagulopathy.

Regarding isolated subsegmental PE, if the patient has no evidence of DVT on bilateral lower extremity ultrasonography, no signs of cardiopulmonary stress (eg, normal biomarkers, normal ECG), and no ongoing major risk for thrombosis (eg, active malignancy, atrial fibrillation), it is reasonable and prudent to withhold anticoagulation for patients with isolated subsegmental filling defects on CTPA. If a patient with a negative CTPA scan has ongoing dyspnea and signs of pulmonary hypertension—enlarged right ventricle, enlarged pulmonary artery, or reflux of contrast into the liver, the mosaic pattern, acute pulmonary hypertension on the ECG—or hypoxemia without an apparent alternative cause, at minimum, the patient should have transthoracic echocardiography performed. If this demonstrates pulmonary hypertension or right ventricular overload, the patient should be referred or admitted to a pulmonary specialist to guide further testing.

Recent evidence has indicated that up to 50% of outpatients diagnosed with PE may be stable enough to be treated as outpatients (low-risk criteria; see Table 78.4). In settings where good follow-up can be obtained, and the patient can be taught to self-administer LMW heparin and can access an anticoagulation clinic within 48 hours, a low-risk patient with PE can be discharged from the ED. My choice, however, is to implement a protocol that includes the Hestia criteria to select low-risk patients (see Box 78.1), together with monotherapy with apixaban or rivaroxaban; this has been associated with low rates of complications and economic advantages.

For a patient diagnosed with PE in the presence of a major contraindication to anticoagulation, such as a recent cerebral hemorrhage or large cerebral infarction, or brain metastases, the appropriate consultant should be contacted for urgent placement of an inferior vena cava filter. If vena caval interruption cannot be performed within 12 hours, one option is to perform a baseline head CT scan, start an unfractionated heparin infusion at 18 U/kg/hr (without a bolus), and admit the patient to the intensive care unit for close neurologic monitoring and frequent partial thromboplastin time (PTT) determinations. The rationale for using unfractionated heparin is that it can be reversed more reliably by discontinuing the heparin drip and administering protamine, 1 mg/kg IV, than fractionated heparin. Case reports and series have suggested that inhaled nitric oxide might be helpful for patients with severe PE and an absolute contraindication to anticoagulation, but this treatment has not yet been subjected to rigorous study.

Most patients with PE state that they feel better the day after starting heparin anticoagulation, and more than half go on to nearly a full recovery of pre-PE health status. The in-hospital mortality rate of patients diagnosed with PE who remain hemodynamically stable while in the ED was thought to be 10%, but a recent large, multicenter, US-based registry of 1880 patients diagnosed with PE in the ED found the in-hospital mortality rate directly attributable to PE to be 1.1% and an all-cause mortality rate of 5.4%. Approximately 10% to 20% of PE survivors complain of persistent dyspnea and exercise intolerance that permanently degrades their quality of life.

Fibrinolytic (Thrombolytic) Therapy

Fibrinolytic therapy in PE remains a controversial treatment option. Recent meta-analyses of randomized trials that compared fibrinolysis plus heparin to heparin alone have reached different conclusions about mortality benefit, with one study finding significant improvement and another no difference in mortality. Most experts, even those generally opposed to fibrinolysis, believe that patients with arterial hypotension (systolic blood pressure < 90 mm Hg) or >40 mm Hg drop from baseline) should receive full-dose systemic fibrinolysis (100 mg of alteplase over 2 hours or tiered-dose tenecteplase, per the TNKase label). No one doubts that the bleeding risk increases with systemic fibrinolysis, but the risk of intracranial hemorrhage appears to be mostly confined to patients older than 65 years. The “to lyse or not to lyse PE” controversy has been made more complex by recent studies suggesting a possible lower risk of significant hemorrhage associated with the lower, half-dose alteplase (50 mg over 2 hours), administered by peripheral vein. Moreover, many large treatment centers have adopted the use of catheter-directed thrombolysis, which administers the fibrinolytic directly into the thrombus, with or without adjunctive ultrasonic energy. The potential advantage of this approach is a lower risk of hemorrhage due to the lower dose of fibrinolytic agent (eg, 20–25 mg of alteplase infused intrathrombus over 24 hours.) No evidence has yet demonstrated a survival advantage or any patient-oriented advantage of catheter-directed therapy. However, one small randomized trial has demonstrated improved quality of life end points with bolus administration of tenecteplase for severe submassive PE.

The clinical course of patients with obstructive PE can be unpredictable. Many patients with massive PE remain stable in the ED. Other patients are stable on arrival, but progressively deteriorate over hours as right ventricular function declines. Of ED patients without hypotension, 3% experience cardiac arrest while in the ED and die within 24 hours. A patient can be stable and then hypotensive within minutes because of the highly variable effect of the clot on right ventricular outflow obstruction, especially when it straddles the main pulmonary artery (Fig. 78.12). Additional mechanisms of rapid instability include new embolization of clot material, release of mediators of pulmonary vasospasm, sudden bradyasystolic arrhythmias, and respiratory
narrow-complex tachycardia to an incomplete right bundle branch block to a complete right bundle branch block (Fig. 78.13) is evidence of life-threatening pulmonary hypertension and impending cardiac arrest.

Clinical evidence of impending or actual respiratory failure indicates the need for prompt endotracheal intubation using a standard rapid sequence intubation technique, preferably with ketamine or etomidate for induction of anesthesia with neuromuscular blockade. Other induction agents that depress cardiac function or reduce preload may precipitate severe hypotension and should be avoided or their dosage reduced. The effect of biphasic, positive pressure-assisted noninvasive ventilation (BiPAP) on hemodynamics with massive PE has not been studied. For patients with PE and persistent hypotension, the role of volume loading to resuscitate massive PE remains uncertain. Most experts use norepinephrine as the vasopressor of choice to attempt to increase blood pressure. In the case of impending respiratory or cardiac arrest, fibrinolytic therapy should be strongly considered.

**Surgical Embolectomy**

For patients with known floating thrombi in the right heart or patients with severe refractory hypotension, surgery is the most likely intervention to save the patient’s life. Surgical embolectomy commonly includes extracorporeal cardiopulmonary bypass and an experienced cardiothoracic surgeon. Surgical embolectomy may be the best option for patients who have severe PE with a contraindication to fibrinolysis; however, extracorporeal perfusion requires intensive heparin anticoagulation, and the patient’s mental status cannot be monitored during surgery—a key concern in patients with a high risk of intracranial hemorrhage.

Numerous case reports have suggested heroic results from the bolus administration of thrombolytic therapy to patients with cardiac arrest from PE. The administration of fibrinolytic therapy does not absolutely preclude surgical intervention. Patients who have been treated with a fibrinolytic agent can undergo sternotomy or thoracotomy for embolectomy and survive without fatal hemorrhage. The decision to perform embolectomy ultimately resides with the cardiac surgeon.

**Disposition**

Table 78.5 summarizes the criteria that can be used to risk-stratify patients with PE into four groups. This stratification may help guide the decision to place the patient in an intensive care unit versus an intermediate or regular inpatient bed and whether to administer heparin only or consider escalated therapy (see Fig. 78.11).
Fig. 78.13. Serial electrocardiograms obtained 2 minutes apart show the progression from a narrow complex rhythm (A) to a right bundle branch block pattern (B) in a patient with massive bilateral pulmonary emboli. Shortly after the second tracing was obtained, the patient developed cardiovascular collapse refractory to vigorous resuscitation efforts.

<tr>
<th>CATEGORY</th>
<th>CRITERIA</th>
<th>ACTION</th>
</tr>
</thead>
</table>
| Low-risk PE | • sPESI of 0⁹⁹  
• Hestia criteria negative (see Box 78.1)⁹⁰  
• SBP > 90 mm Hg at all times and all of the following: no proximal clot or RV dilation on CTPA, shock index < 1, SaO₂ > 94%, no pulmonary hypertension on ECG (Daniel score < 3), normal troponin, BNP, or pro-BNP level  | • Begin anticoagulant treatment (see Table 78.3)  
• Optional admission to unmonitored regular bed  
• Consider outpatient treatment if adequate Compliance and follow-up can be assured |
| Moderate-risk PE | • SBP > 90 mm Hg at all times and any one of the following:  
Proximal clot and RV > LV on CTPA scan (see Fig. 78.12)⁷⁸,⁸⁴,⁸⁵,⁸⁸  
Elevated troponin or BNP level (>90 pg/mL) or pro-BNP level (>900 pg/mL)  
Echocardiogram with any degree of right ventricular hypokinesis  | • Begin anticoagulant treatment (see Table 78.3)  
• Fibrinolytics in minority of cases  
• Admission to a telemetry bed |
| More severe (submassive); moderate-risk PE | • Any moderate risk criteria and appearance of at respiratory distress  
• Shock index > 1 and severe right ventricular hypokinesis on echocardiography  
• Worsening Daniel score, particularly a new incomplete right bundle branch block (RBBB) or progression of incomplete RBBB to complete RBBB  
• SaO₂ < 90% and serum troponin level clearly elevated  
• New altered mental status  | • Begin heparin treatment  
• Fibrinolytic treatment in most patients without contraindications in the ED  
• Admission to a step-down or intensive care unit |
| High-risk (major) PE | • Any SBP <90 mm Hg or <20 mm Hg below documented baseline and appearance of distress  
• Any persistent SBP <90 mm Hg, regardless of appearance  | • Begin heparin treatment  
• Fibrinolytic treatment in all patients without contraindications in the ED  
• Admission to intensive care unit |

*BNP*, Brain natriuretic peptide; *CTPA*, computed tomography pulmonary angiography; *ED*, emergency department; *PE*, pulmonary embolism; *RBBB*, right bundle branch block; *RV/LV*, right ventricle–left ventricle ratio; *SBP*, systolic blood pressure.
Deep vein thrombosis often presents as a nonspecific crampy sensation in the upper or lower extremity without obvious swelling.

An ELISA or immunoturbidimetric D-dimer concentration less than 500 ng/mL can exclude DVT in patients with a low pretest probability (PTP).

A negative three-point ultrasound, together with a negative quantitative D-dimer test result, excludes DVT with any PTP.

A negative three-point ultrasound in a patient with a moderate or high PTP for DVT should have additional testing, including a D-dimer test or repeat venous ultrasound within 3 to 7 days.

An enzyme-linked immunosorbent assay (ELISA) or immunoturbidimetric D-dimer concentration less than 500 ng/mL can exclude DVT with any PTP.

A patient at a low PTP may have the diagnosis of DVT effectively excluded by a negative three-point venous duplex ultrasound performed by a qualified emergency clinician or radiologist.

A single, whole-leg ultrasound excludes DVT in all pretest probabilities.

When duplex ultrasound is not available, patients with a moderate to high PTP for DVT should receive empirical LMW heparin, oral apixaban, or rivaroxaban while awaiting the availability of ultrasound imaging; patients with a low PTP, or moderate to high PTP with a negative D-dimer, do not need empirical anticoagulation while they wait for diagnostic imaging.

Patients at a low or moderate PTP for PE should have a D-dimer test done prior to performing pulmonary vascular imaging; PE can be ruled out in non–high PTP, with a D-dimer adjusted for age according to this formula: age × 10 ng/mL.

A patient with a PTP less than 2% need not be tested for PE.

Patients with PE and low risk according to the Hestia criteria (see Box 78.1) can be treated at home, provided they have adequate follow-up.

Patients with PE and arterial hypotension (systolic blood pressure < 90 mm Hg) should receive systemic fibrinolysis unless they have a contraindication to fibrinolysis.

CHAPTER 78: QUESTIONS & ANSWERS

78.1. Which of the following statements concerning the D-dimer protein level is most true?
A. It is derived from the enzymatic breakdown of thrombin.
B. It is elevated in patients with acute febrile illness.
C. The concentration is higher in smokers but unaffected by advancing age.
D. The concentration is proportional to the size of the clot.
E. The serum half-life is 48 to 60 hours, making it sensitive for older clots.

Answer: D. The D-dimer concentration varies directly with clot burden. It is derived from the enzymatic breakdown of fibrin, with a serum half-life of 8 hours, making it less sensitive for older, more mature clots. Levels are not higher in smokers but may be elevated with advanced age and immobility. It is not elevated by febrile illness.

78.2. What is the sensitivity of venous duplex ultrasonography for detecting a proximal DVT?
A. 80%
B. 85%
C. 90%
D. 95%
E. 100%

Answer: D. The sensitivity of a single scan is 95%. Thus, 5% are missed.

78.3. A 29-year-old woman presents with onset of left calf pain and mild swelling over a 24-hour period. She is 26 weeks pregnant, with no other medical problems and no other symptoms. The D-dimer level is 845 ng/mL. Lower extremity duplex ultrasonography is negative. What would be the most appropriate course of action?
A. Contrast CT scanning of the chest
B. Empirical anticoagulation
C. Repeat ultrasound in 2 or 3 days
D. Repeat ultrasound in 24 hours
E. V/Q scan of the chest

Answer: C. In moderate- to high-risk patients with an elevated D-dimer level, a single ultrasound may be insufficient. A repeat study in 2 to 7 days is often sufficient to confirm the diagnosis. The lack of pulmonary symptoms precludes the need for lung and embolus evaluation at this time. During pregnancy, there is a progressive rise in baseline D-dimer concentration; thus, a normal value is useful but an elevated level is of no discriminatory value.

78.4. A 43-year-old woman presents with acute pain and swelling of her right saphenous vein. Symptoms have occurred over 48 hours. She does not smoke and has no significant past medical history. Vital signs are unremarkable, and the physical examination is also unremarkable, except for isolated swelling, erythema, tenderness, and increased firmness along the track of the right saphenous vein from the malleolus to 4 cm below
the tibial plateau. There is no calf or thigh swelling or tenderness. Which of the following would be appropriate management?

A. Nonsteroidal antiinflammatory drugs (NSAIDs) and compression stockings
B. Antistaphylococcal antibiotics and antiinflammatory agents
C. Antistaphylococcal antibiotics and elevation for 24 to 48 hours
D. Systemic anticoagulation
E. Ultrasonography to rule out DVT, then antiinflammatory agents and compression stockings

Answer: E. Many patients with superficial thrombophlebitis have a synchronous DVT. Once ruled out, treatment is symptomatic, with NSAIDs and compression stockings. Ambulation is encouraged. Routine anticoagulation is not indicated for superficial thrombophlebitis.

78.5. A 46-year-old woman presents with pain and swelling of the right calf. She has a history of tobacco use, emphysema, and hypertension. Medications are albuterol inhaler, lisinopril, 20 mg/day, and oral contraceptives. She denies pulmonary or cardiac symptoms. Vital signs and the physical examination are unremarkable except for pain and tenderness to palpation, with minimal swelling of the right calf. Doppler ultrasonography reveals an isolated calf thrombosis. What is the appropriate management?

A. Aspirin therapy with repeat Doppler in 2 to 7 days
B. Intravenous fibrinolysis with tenecteplase
C. Nonsteroidal anti inflammatory agents and compression stockings
D. Reassurance
E. Systemic anticoagulation

Answer: E. Approximately 25% of isolated calf DVTs propagate proximally. Serial Dopplers as surveillance for proximal propagation may be acceptable in healthy ambulatory patients, but full anticoagulation, as for DVT, would be the safest course of action for this patient.

78.6. Which of the following statements concerning upper extremity DVTs is true?

A. After appropriate treatment, it is rare for symptoms to persist long term after upper extremity DVT.
B. Anticoagulation is not always necessary in upper extremity DVT.
C. If present, indwelling catheter removal is required for successful DVT treatment.
D. Other than catheter-related cases, most occur in patients who are young and healthy.
E. The rate of pulmonary embolus from axillary vein DVT is lower than that from the femoral vein.

Answer: D. So-called effort thrombosis is often seen in healthy patients after vigorous exercise. Many of these are later found to have anatomic abnormalities relating to the subclavian and axillary vein. Approximately 50% of upper extremity DVTs are related to indwelling catheters. Catheter removal is not always mandatory. Appropriate treatment for upper extremity DVT includes full anticoagulation and is sometimes accompanied by fibrinolysis or thrombectomy. The incidence of pulmonary embolus is the same as for femoral DVTs. Many patients remain symptomatic, with ongoing arm pain and swelling, despite appropriate treatment.

78.7. In a young healthy patient, what percentage of the cross-sectional area of the pulmonary vascular bed can be acutely occluded with only minimal symptoms?

A. 10%
B. 20%
C. 30%
D. 40%
E. 50%

Answer: C. Again, this assumes a patient with full cardiopulmonary reserve and no preexisting disease.

78.8. What percentage of patients with pulmonary embolus may present with a normal (98%–100%) pulse oximetry reading on room air?

A. 5%
B. 10%
C. 15%
D. 20%
E. 25%

Answer: B. A low oxygen saturation (<95%) increases the probability of pulmonary embolus, but a normal oxygen saturation should not dissuade one from the diagnosis.

78.9. What percentage of patients diagnosed with pulmonary embolus have no apparent clinical risk factor for venous thromboembolism?

A. 10%
B. 20%
C. 30%
D. 40%
E. 50%

Answer: E. The point here is that being healthy does not rule out the possibility of VTE. Risk factors are best applied to population analysis and are of very limited use when evaluating a single patient.
Swallowing is divided into oral, pharyngeal, and esophageal phases. Precise motor control of the act of swallowing is necessary to ensure that food is successfully transferred from the mouth through the esophagus into the stomach. Failure at any one of these levels results in dysphagia, which literally means “difficulty swallowing.”

Dysphagia at any age is abnormal; it is particularly common in older adults, with up to 60% of assisted living and nursing home patients having reported difficulty feeding. Dysphagia is classified as two types, oropharyngeal and esophageal. Oropharyngeal dysphagia, also termed transfer dysphagia, involves difficulty transferring a food bolus from the oropharynx to proximal esophagus. Esophageal dysphagia involves difficulty in transporting material down the esophagus.

Oropharyngeal Dysphagia. Neuromuscular disease causes approximately 80% of cases of oropharyngeal dysphagia, with most remaining causes being localized structural lesions. Most neuromuscular causes of dysphagia result in misdirection of the bolus, sticking, and the need for repeated swallowing attempts. Liquids, especially of extreme temperatures, cause dysphagia more commonly than solids, and symptoms are often intermittent. Cerebrovascular accidents causing pharyngeal weakness with failure of the cricopharyngeus muscle to relax is the most common cause of neuromuscular dysphagia. Dysphagia at any age is abnormal; it is particularly common in older adults, with up to 60% of assisted living and nursing home patients having reported difficulty feeding. Dysphagia is classified as two types, oropharyngeal and esophageal. Oropharyngeal dysphagia, also termed transfer dysphagia, involves difficulty transferring a food bolus from the oropharynx to proximal esophagus. Esophageal dysphagia involves difficulty in transporting material down the esophagus.

Esophageal Dysphagia. Esophageal dysphagia is caused by mechanical lesions or a motility disorder. Mechanical lesions may be intrinsically or extrinsically to the esophagus. Intrinsically, lesions include strictures, webs, rings, tumors, esophagitis, postsurgical changes, and esophageal foreign bodies. Pressure from extrinsic lesions such as osteophytes, mediastinal masses, or aortic aneurysms can also cause dysphagia.

Patients with esophageal dysphagia who have no readily identifiable mechanical cause may have a motor disorder. Intrinsic motor disorders of the esophagus include achalasia, diffuse esophageal spasm, nutcracker esophagus, and hypertensive lower esophageal sphincter (LES). Systemic connective tissue diseases, scleroderma, CREST (calcinosis, Raynaud’s phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia) syndrome, Chagas’ disease, or a paraneoplastic syndrome may cause secondary motor disorders.

Achalasia is a disorder of unknown cause in which the resting pressure of the LES is markedly increased, and peristalsis in the body of the esophagus is absent. The incidence increases with age.

Diffuse esophageal spasm is another type of intrinsic motor disorder and, when it is severe and prolonged, with associated high-intensity peristaltic waves, it is termed nutcracker esophagus.

Non-specific motor disorders include repetitive esophageal contractions, nontransmitted esophageal contractions, and low-amplitude esophageal contractions.

Pathophysiology

Swallowing is a complex phenomenon requiring voluntary and involuntary skeletal muscle activity coordinated by the swallowing center in the medulla. The trigeminal, glossopharyngeal, vagus, and spinal accessory cranial nerves provide afferent sensory inputs; efferent motor activity travels through the trigeminal, facial, glossopharyngeal, vagus, and hypoglossal cranial nerves.

There are intrinsic and extrinsic causes of esophageal stenosis that may lead to symptoms of obstruction. Non-specific motor disorders include repetitive esophageal contractions, nontransmitted esophageal contractions, and low-amplitude esophageal contractions.
The examination should include a thorough evaluation of the head and neck and a detailed neurologic examination. The patient should be observed while swallowing. Difficulty in initiating the swallow, misdirection of the bolus with regurgitation or aspiration, and unusual posturing of the patient when swallowing should be noted. Many patients with neuromuscular disorders depend on gravity to swallow, and having the patient swallow in the prone position may be helpful in making the diagnosis.

Oropharyngeal Dysphagia

Oropharyngeal dysphagia is characterized as an inability or excessive delay in initiation of swallowing, aspiration of the ingestate, nasopharyngeal regurgitation, or residual ingestate within the pharyngeal cavity following a swallowing event. This may be caused by misdirection of the food bolus, pain, or sticking and complicated by multiple swallowing attempts. Symptoms may include discomfort or pain in the cervical region, coughing, choking, drooling, or nasal regurgitation.

Tongue weakness can result in oral regurgitation. Inability to seal the nasopharynx because of obstruction or muscular weakness can cause nasal regurgitation. Inefficient laryngeal elevation from muscular weakness or a fixed larynx can result in laryngotracheal aspiration. Delayed aspiration can occur with pharyngeal weakness and with pooling of food in the piriform recesses or in a diverticulum. Inability to contract the pharyngeal muscles is often compounded by failure of the cricopharyngeus to relax, which causes misdirection of the food bolus or necessitates repeated swallowing attempts. Inflammatory lesions of the tongue or oropharynx can result in odynophagia, which may impede swallowing.

Clinical Features

A careful history helps differentiate oropharyngeal from esophageal dysphagia in up to 85% of patients (Box 79.1). The history focuses on determining the anatomic level involved (oropharyngeal vs. esophageal), types of food causing the symptoms (liquids, solids, or both), and whether the symptoms are intermittent or progressive. Associated pain, past gastrointestinal history, and family history are also helpful in determining the cause.

</table>
Esophageal Dysphagia

Dysphagia from upper esophageal lesions is usually perceived 2 to 4 seconds after the initiation of swallowing. Dysphagia that the patient localizes to the substernal or retrosternal area may be anatomically accurate, but localization to the neck may be referred from anywhere in the esophagus.

Dysphagia is the most common presenting symptom of achalasia and usually begins insidiously, with equal frequency for solids and liquids. Patients may report that maneuvers that increase esophageal pressure (eg, raising arms above the head, standing erect with back straight) help pass the food. Odynophagia from esophageal spasm may also be seen early in the course of achalasia. The symptoms are often worse with rapid eating and during periods of stress. The patient may also report chest pain as a symptom. As dilation occurs above the sphincter, retention of undigested food in the esophagus occurs, and the patient may be aware of gurgling while eating. Regurgitation of the undigested material can occur after a meal, prompting consideration of the diagnosis of an eating disorder, or with changes in position or vigorous exercise. The regurgitated food usually has no acid taste unless bacterial contamination causes fermentation of the undigested food. Laryngotracheal aspiration may occur, especially at night, and may cause nocturnal coughing. The physical examination is usually unremarkable, except for weight loss. Radiographically, a dilated esophagus is seen proximal to a narrowed gastroesophageal junction that has a beaklike appearance.

Esophageal spasm may be precipitated by swallowing very hot or cold liquids. Symptoms include chest pain, dysphagia, or both. Manometrically, simultaneous prolonged strong esophageal contractions are noted to be interspersed over normal peristaltic waves.

If a barium swallow is performed during a spasm, findings such as corkscrewing, or curling, of the esophagus may be noted.

Differential Diagnosis

The differential diagnosis of esophageal dysphagia includes acute coronary syndrome (ACS). Substernal chest pain is the main symptom in 80% to 90% of patients with esophageal motility disorders. The chest pain can be similar to angina, described as crushing or squeezing, with patterns of radiation similar to those of cardiac chest pain. Nitroglycerin may also relieve the pain of spasm, further confusing the picture.

Symptoms that suggest an esophageal cause of chest pain are pain that is prolonged and nonexertional, pain that interrupts sleep, pain related to meals, relief with antacids, and presence of other symptoms of esophageal disease, such as heartburn, dysphagia, or regurgitation. Because of considerable overlap in symptoms, a cardiac diagnosis must be excluded before attributing chest pain to an esophageal cause.

Diagnostic Testing

The history and physical examination direct the need for testing. Nasopharyngoscopy is used to assess for upper structural abnormalities. The decision and timing of swallowing studies (eg, video esophagography), barium swallows, manometry, and impedance monitoring are best coordinated with consultants. These studies are rarely indicated in the emergency department (ED). However, patients who are unable to swallow safely or maintain adequate hydration should be admitted for further evaluation.

Management

Achalasia is the only motility disorder for which reasonably good studies support specific treatment. Pharmacologic therapy is directed at decreasing the tone of the LES. Nitrates and calcium channel blockers have been tried, but adverse effects limit their usefulness. Other therapies used with some degree of success have included botulinum toxin injection, pneumatic dilation, and surgical intervention.

Medical therapy for esophageal motility disorders is limited, and clinical results are usually minimal. Anticholinergic drugs such as hyoscyamine sulfate or dicyclomine have been used because they decrease the amplitude of esophageal peristalsis and LES pressure. However, because these drugs delay gastric emptying and decrease esophageal peristalsis, they may exacerbate reflux symptoms. Other therapies include the use of calcium channel blockers, which decrease LES pressure and amplitude of esophageal contractions.

Disposition

Patients at risk of aspiration or who are unable to hydrate are candidates for hospital admission. Otherwise, prompt outpatient evaluation by a gastroenterologist is indicated.

FOREIGN BODIES

Principles

Background

Patients with esophageal foreign bodies are classified into four major groups: (1) pediatric patients; (2) psychiatric patients and prisoners; (3) patients with underlying esophageal disease; and (4) edentulous adults. Pediatric patients account for more than 75% of cases, with the peak incidence occurring in those between the ages of 18 and 48 months. Swallowing coins accounts for most cases of pediatric ingestion, whereas most adult impactions involve food, particularly meat and bones. Patients with structural abnormalities of the esophagus are at greater risk for foreign body impaction. Edentulous adults are also at increased risk because of impaired oral sensation, which may contribute to their risk of accidental ingestion of the dental prosthesis.

Anatomy and Physiology

The esophagus begins in the hypopharynx, approximately at the level of the cricoid cartilage. On either side of this cephalad slit are the piriform recesses, which are blind pouches that may occasionally harbor a foreign body. There are four natural areas of narrowing where most foreign bodies become entrapped—at the cricopharyngeus muscle (upper esophageal sphincter [UES]), aortic arch, left mainstem bronchus, and LES at the diaphragmatic hiatus. Pediatric entrapment occurs primarily at the level of the cricopharyngeus, whereas adult entrapment occurs mainly at the UES (Fig. 79.1).

The esophagus comprises two main bands of muscle, an inner circular layer and outer longitudinal layer. The resting tone of these muscles causes the inner epithelium to fold in on itself, effectively obliterating the lumen. Elastic fibers enable the esophageal lumen to expand and allow passage of a food bolus. The upper third of the esophagus, including the cricopharyngeus muscle, contains striated muscle to allow for the voluntary initiation of swallowing. The middle portion of the esophagus is a mixture of skeletal and smooth muscle, and the distal third is composed only of smooth muscle. Although it is relatively fixed at its origin, the esophagus becomes mobile as it traverses the mediastinum and can be easily displaced by adjacent structures. An enlarged left atrium or ventricle, goiter, or mediastinal tumor may cause enough displacement of the esophagus to impede the passage of a food bolus or foreign body.
PART III
Anatomic

Pathophysiology
Although obstruction may occur in a patient with a normal esophagus, preexisting structural abnormalities such as strictures (peptic or malignant), distal esophageal mucosal rings, or eosinophilic esophagitis are identified in almost 90% of patients with an esophageal obstruction. Schatzki’s ring is a specific type of mucosal ring present in 15% of the population and characterized by a fibrous, diaphragm-like stricture near the gastroesophageal junction.

Clinical Features
Patients with an esophageal obstruction have a wide range of symptoms that typically begin minutes to hours after the ingestion. Most adults are able to describe the precipitating event and clinical status of the patient. Flexible endoscopy using procedural sedation is recommended in most cases of complete esophageal obstruction, because rigid endoscopy requires general anesthesia and has a higher complication rate.

Diagnostic Testing
In most cases, the patient’s history will be all that is necessary to confirm the diagnosis and begin therapeutic intervention. Imaging studies may be needed in unknown or equivocal cases or in patients who are unable to give a history. Anteroposterior (AP) and lateral radiographs of the neck, chest, and abdomen are indicated when a radiopaque foreign body is suspected. Flat objects in the esophagus such as coins or button batteries typically orient in the coronal plane and appear as a circular object on an AP projection (Fig. 79.2). Button batteries can be differentiated from coins by a characteristic radiographic double-density appearance. Small bones or radiopaque objects may occasionally be visualized. Radiographs are unreliable for detecting a fish bone.

Nasopharyngoscopy is useful in differentiating a retained foreign body from a mucosal abrasion. In the vast majority of these patients, no fish bone is identified. Air in the tissues may be present if perforation has occurred. However, failure to demonstrate a foreign body on radiographs does not rule out its presence. Persistent or concerning symptoms in a patient without evidence of a radiographic foreign body can be further evaluated by laryngoscopy and endoscopy.

Contrast studies with barium or gastrografin are rarely performed to evaluate for a foreign body because they present a risk for aspiration and can obscure visualization if subsequent endoscopy is necessary. Computed tomography (CT) may be used in equivocal cases to identify and localize foreign bodies before endoscopy. CT is more sensitive than radiography for identifying foreign bodies, including chicken or fish bones and other nonorganic objects. CT scans have the additional value of visualizing changes associated with perforation in the surrounding tissues.

Management
Treatment for esophageal foreign bodies depends on the type and location of the object and clinical status of the patient. Flexible endoscopy using procedural sedation is recommended in most cases of complete esophageal obstruction, because rigid endoscopy requires general anesthesia and has a higher complication rate.

Urgent intervention is indicated for button batteries, large or sharp objects, coins lodged in the proximal esophagus, impactions that impair the handling of secretions, and food boluses causing signs of high-grade esophageal obstruction. Factors associated with a risk of complications included a longer duration of impaction, bone foreign bodies, and larger foreign bodies.

Although it is acceptable to delay endoscopy briefly in stable patients without high-grade obstruction to allow possible spontaneous passage, the American Society for Gastrointestinal Endoscopy has recommended that food boluses causing incomplete obstruction be removed within 24 hours. Any object remaining in...
the esophagus for more than 24 hours carries a higher risk of complications, including perforation, aortoenteric fistula, tracheoesophageal fistula, and abscess. These complications may occur up to years after the ingestion. Follow-up endoscopic evaluation after an esophageal obstruction is necessary to rule out underlying pathologic conditions.

Upper Esophagus

Oropharyngeal foreign bodies can often be removed with a Kelly clamp or Magill forceps under direct visualization. Smooth upper esophageal foreign bodies such as coins can often be removed with a Foley catheter. This procedure requires an experienced clinician, cooperative patient, and fluoroscopic guidance. The patient is placed in a prone position, and the catheter is passed into the esophagus past the point of the foreign body impaction. The balloon is then inflated and the catheter withdrawn, pulling the foreign body with it. The literature reports that up to 80% of foreign bodies are successfully removed with this technique, and an additional 8% advance into the stomach. Failure rates are highest with infants younger than 1 year. Controversy exists regarding the safety of this technique because there is no direct control of the foreign body. However, large studies have shown complication rates to be less than 1% when patients are carefully chosen.

Foley catheter removal should not be used for a foreign body that has been impacted for more than 1 week, for objects that are not smooth, for patients with radiographic evidence of esophageal perforation, or for patients with any underlying structural esophageal abnormalities. This technique has a significant economic advantage when compared with the costs of general anesthesia in an operating room for the performance of rigid endoscopy.

Another technique is bougienage, which has been shown to be safe and effective in coin removal. In this technique, an esophageal dilator is passed through the mouth into the esophagus to advance the coin into the stomach; the dilator is then quickly removed. In a large study, this procedure took less than 5 seconds to perform and was successful in 95% of cases, with no serious complications.

Lower Esophagus

Lower esophageal obstruction is usually the result of an impacted food bolus. Anecdotally, intravenous (IV) administration of 1 mg of glucagon, up to a total of 2 mg, can cause enough relaxation of the esophageal smooth muscle to allow passage of a food bolus into the lower esophagus. However, the results of studies assessing the effectiveness of this treatment are mixed, and the only double-blind, placebo-controlled study found it to be ineffective. Moreover, glucagon can cause vomiting, which can increase the risk of aspiration or esophageal perforation. Based on lack of evidence and the potential risks, we do not recommend using glucagon in the management of esophageal foreign bodies. IV benzodiazepines have anecdotally been used as a first-line approach for stable patients with a meat impaction, but the evidence supporting their benefit is sparse and suggests that their effectiveness is not better than a placebo.

Small studies have examined the role of effervescent agents in treating food boluses. They have shown no clear evidence of benefit, and there is a theoretic potential of inducing perforation.

---

**Fig. 79.2.** Appearance of coin and button battery foreign body on x-ray. A, Coin in the upper esophagus. B, Appearance of button battery on x-ray. C, Frontal comparison of coin and button battery.
of a possibly ischemic distal esophagus in cases of a complete obstruction. Similarly, the use of meat tenderizer (papain) to soften a food bolus is potentially dangerous and should not be used.

Endoscopy should be performed immediately for patients experiencing distress and for children with impaction of an alkaline button battery. Battery buttons lodged in the esophagus can cause severe tissue damage in just 2 hours. Damage is primarily related to localized corrosive effects and occurs by three main mechanisms—leakage of an alkaline electrolyte, pressure necrosis, and generation of an external current that causes electrolysis of tissue fluids, thus generating hydroxide at the battery’s negative pole. Larger batteries carry a greater risk of impaction and leakage. Delayed complications include esophageal perforation, tracheoesophageal fistula, esophageal strictures, and exsanguination after the development of a fistula with a major blood vessel. In a review of over 8000 battery ingestions that were reported to the National Battery Ingestion Hotline, outcomes have significantly worsened over the past decade. This is primarily attributable to the newer 20-mm-diameter lithium cell batteries that now account for 92% of fatal ingestions.

Batteries that pass into the stomach should be followed radiographically and clinically to ensure passage. Assistance with the management of a patient with button battery ingestion can be obtained through the National Button Battery Ingestion Hotline (1-202-625-3333) or at www.poison.org/prevent/battery.asp.

Stomach

Conservative outpatient management is appropriate for the vast majority of foreign bodies that have entered the stomach. However, certain foreign bodies that pass into the stomach still require endoscopic retrieval. Objects longer than 5 cm or wider than 2.5 cm in diameter (eg, toothbrushes, spoons) rarely pass the duodenum. All sharp and pointed foreign bodies (eg, toothpicks, bones) should be removed before they pass out of the stomach because there is a risk of intestinal perforation. Smaller objects that pass into the stomach can be followed with stool inspections and serial radiographs, if necessary, to confirm passage. Surgical removal should be considered for objects that remain in the stomach for more than 3 to 4 weeks or that remain in the same intestinal location for more than 1 week.

Disposition

The patient with an esophageal or stomach foreign body requires a gastroenterology consult and consideration for upper endoscopy for foreign body removal. The patient should not be discharged to home until the foreign body has been removed or deemed safe to allow transit through the intestines. Patients who undergo endoscopy should be observed until awake from sedation and able to tolerate oral intake. These patients should be discharged with a proton pump inhibitor and plan for repeat upper endoscopy to identify potential structural abnormalities. If no foreign body is found, and the patient is able to swallow liquids, she or he may be safely discharged, with outpatient follow-up.

ESOPHAGEAL PERFORATION

Principles

Background

Esophageal perforation can result from a rapid increase in intraluminal pressure related to forceful vomiting or any Valsalva-like maneuver, including childbirth, coughing, and heavy lifting. Iatrogenic esophageal perforation can result during manipulation of the esophagus, such as during endoscopy, nasogastric tube placement, or endotracheal intubation. Other causes of perforation include foreign body ingestion, caustic substance ingestion, severe esophagitis, carcinoma, and direct injury related to blunt or penetrating trauma. Spontaneous rupture occurs because of a rapid increase in intraluminal esophageal pressure through a patent LES.

Anatomy and Physiology

More than 90% of spontaneous esophageal ruptures occur in the distal esophagus. In contrast, rupture resulting from blunt trauma to the neck or thorax usually occurs in the proximal and middle thirds of the esophagus. Most iatrogenic injuries occur at the pharyngoesophageal junction because the wall in this area is thin, there is no serosal layer to reinforce it, and force is frequently used to pass the tube beyond the level of the cricopharynx. Another site of frequent iatrogenic injury is the esophagogastric junction. In this area, the esophagus curves anteriorly and to the left as it enters the abdomen, and an endoscope has a greater likelihood of perforating the posterior wall. This usually occurs during therapeutic dilation for strictures or achalasia.

Clinical Features

Clinical presentations of esophageal perforation vary and depend on the cause, location, size, and degree of contamination. Symptoms related to iatrogenic perforation may not appear until several hours after the procedure. Patients with an upper esophageal perforation usually have neck or chest pain, dysphagia, respiratory distress, and fever. Odynophagia, nausea, vomiting, hoarseness, and/or aphonia may also result. Mackler’s triad of subcutaneous emphysema, chest pain, and vomiting is considered pathognomonic for spontaneous esophageal rupture. However, the complete triad is seen in less than 50% of cases.

Patients with perforation of the lower esophagus may have abdominal pain, pneumothorax, hydropneumothorax, and pneumomediastinum. The pain may radiate to the back, left side of the chest, and left or both shoulders. Physical findings include epigastric or generalized abdominal tenderness, often with involuntary guarding and rigidity. Up to 30% of patients develop mediastinal or cervical emphysema, which may be noted by crepitus on palpation or by the pathognomonic Hamman’s sign, with a crunching sound heard during auscultation. Patients with severe mediastinitis may be in fulminant shock.

Differential Diagnosis

Misdiagnosis occurs in more than 50% of patients with esophageal perforation or rupture because of the broad differential diagnosis of chest and abdominal pain. This includes pulmonary embolism, acute myocardial infarction, aortic dissection, perforated ulcer, pneumothorax, lung abscess, pericarditis, and pancreatitis. Esophageal perforations should be diagnosed as soon as possible because the morbidity and mortality associated with unrecognized perforations dramatically increase with time.

Diagnostic Testing

Chest and upright abdominal radiography is generally the first diagnostic study performed in patients suspected of an esophageal perforation. Radiographic abnormalities may be detected in up to 90% of patients with esophageal perforation (Fig. 79.3). Patients with upper esophageal injuries commonly have chest radiographs that show pneumomediastinum alone or a right-sided pleural effusion, whereas patients with distal esophageal perforations...
ESOPHAGITIS

Principles

Esophagitis is an inflammation of the esophagus. The most common cause is gastroesophageal reflux disease (GERD). Other important causes include eosinophilic infiltration, infection, foreign body or toxic ingestion, and radiation. Chapter 148 discusses esophagitis caused by caustic substance ingestion.

Gastroesophageal Reflux Disease

Asymptomatic reflux of gastric contents from the stomach into the esophagus occurs in most people several times a day as a normal physiologic phenomenon. GERD occurs when reflux becomes symptomatic or causes histopathologic alterations in the upper gastrointestinal (GI) or respiratory tract. In the United States, symptomatic reflux in the form of heartburn occurs daily in 7% of adults, weekly in 14%, and monthly in 40%.

The primary mechanism that enables reflux of gastric contents into the esophagus is an inappropriate relaxation of the LES. This can occur because of general hypotension of the LES, increased intraabdominal pressure, or transient LES relaxations. Multiple risk factors can decrease LES pressure and lead to reflux, including medications (eg, nitrates, calcium channel blockers, anticholinergics, albuterol), fatty meals, and chocolate. Other mechanisms that may contribute to GERD include esophageal motility abnormalities, increased intragastric pressure (eg, obesity, pregnancy), acid hypersecretion, gastric outlet obstruction, and conditions that cause delayed gastric emptying (eg, gastroparesis, neuromuscular disease).

Repetitive exposure to acid can lead to changes in the esophageal mucosa. Continued reflux can lead to thinning of the normal stratified squamous epithelial layer. With the development of esophagitis, an inflammatory response occurs in the mucosa and submucosa, with infiltration of polymorphonuclear leukocytes. The inflammatory response is the result of chemical irritation of the esophageal mucosa from reflux of gastric acid, pepsin, and bile acids. Both acid and alkaline refluxes produce the same pathologic changes. Continued exposure can lead to further endoscopically visible changes of erosion, ulceration, and scarring. Ultimately, stricture formation may result. The most severe histologic consequence of GERD is replacement of the normal stratified squamous epithelium with metaplastic columnar epithelium in a condition termed Barrett’s metaplasia. In patients with reflux undergoing endoscopy, approximately 10% to 15% are found to have Barrett’s esophagus. There is a strong correlation between the development of Barrett’s metaplasia and adenocarcinoma of the esophagus.

Management

Clinically unstable patients with esophageal perforation require rapid resuscitation and treatment. Broad-spectrum IV antibiotics should be initiated early; we recommend vancomycin 15 mg/kg and piperacillin-tazobactam, 3.375 g. Patients should receive nothing by mouth (NPO), and early surgical consultation is warranted. Treatment within the first 24 hours has been found to improve survival when compared to delayed treatment.

There is evidence that some iatrogenic perforations in select patients at low risk can be managed conservatively. These patients typically have a left-sided effusion. Other radiographic abnormalities include subcutaneous emphysema, mediastinal widening, and pulmonary infiltrates. These radiographic changes are often not present in the first few hours after perforation, so a normal early radiograph should not be used to exclude the possibility of esophageal perforation.

Patients with possible perforation should undergo contrast radiographic studies. Barium sulfate is superior for identifying small perforations, but may incite an inflammatory response in tissues. Water-soluble agents (eg, Gastrografin) may be safer but they are less dense and may not demonstrate the abnormality. In addition, pneumonitis may result if these agents are aspirated because of their hypertonicity. We recommend an initial attempt with a water-soluble agent for patients who are not at risk for aspiration. If a perforation is not identified and suspicion is high, a second study with barium is recommended.

CT of the chest may be considered if a contrast study does not demonstrate a clinically suspected perforation. It can also be used in patients who are intubated or cannot complete esophagography. Findings such as mediastinal air, extraluminal contrast material, or fluid collections or abscesses adjacent to the esophagus confirm a perforation. CT also allows for the evaluation of other adjacent areas that may suggest an alternative diagnosis.

Flexible esophageal endoscopy is useful in directly visualizing the perforation, especially in cases of penetrating external trauma. It can also be used in patients who are intubated or cannot complete esophagography. Findings such as mediastinal air, extraluminal contrast material, or fluid collections or abscesses adjacent to the esophagus confirm a perforation. CT also allows for the evaluation of other adjacent areas that may suggest an alternative diagnosis.

Eosinophilic Esophagitis

Eosinophilic esophagitis results from an eosinophilic infiltration within the esophageal mucosa or deeper tissues. Initially thought to be a disease of children, it is being diagnosed in adults with increasing frequency. The cause is unknown, although there is an association with food allergens, especially in the younger age group. More than 50% of patients have associated atopic disorders, such as asthma or eczema. The criteria necessary for diagnosis of eosinophilic esophagitis are clinical symptoms of esophageal dysfunction, more than 15 eosinophils in one high-power field on esophageal biopsy, and lack of responsiveness to high-dose proton pump inhibitors (PPIs).

Infectious Esophagitis

Esophageal infections primarily occur in immunocompromised hosts. When they occur in healthy patients, there is usually an underlying esophageal abnormality or local area of immune compromise, as might occur with the use of inhaled steroids. Latrogenic alterations in host defenses through the use of immunosuppressive agents, potent chemotherapeutic agents, and broad-spectrum antibiotics can predispose an individual to the development of an esophageal infection. Other systemic diseases that weaken immunologic defenses in otherwise normal hosts can predispose the esophagus to infection, including diabetes mellitus, alcoholism, underlying malignancy, use of corticosteroids, and advanced age. The *Candida* species (primarily *Candida albicans*) are the most common esophageal pathogens.

Human immunodeficiency virus (HIV) is a risk factor for infectious esophagitis, but rates have decreased since the advent of highly active antiretroviral therapy (HAART). Patients with acute HIV seroconversion syndrome that occurs 2 to 3 weeks after primary exposure to HIV can develop esophageal ulcerations and severe odynophagia.

As empirical antifungal prophylaxis in immunosuppressive states has become more common, viral esophagitis has become more prominent. Herpes simplex virus 1 (HSV-1) and cytomegalovirus (CMV) are the most common viral pathogens. Human papillomavirus has been implicated as well. Bacteria, mycobacteria, other fungi, and parasitic organisms such as *Trypanosoma cruzi*, *Cryptosporidium*, and *Pneumocystis* are uncommon causes of infectious esophagitis and are usually diagnosed by culture or biopsy.

Pill Esophagitis

The exact incidence of pill esophagitis is unknown because most cases are unrecognized and therefore unreported. The condition results when a pill or capsule fails to pass into the stomach and remains in contact with the esophageal mucosa for a prolonged period. This results in inflammation and injury of the esophageal mucosa.

Pill esophagitis has been reported in all age groups. Predisposing factors include advanced age, decreased esophageal motility, and extrinsic compression. Large pills are more likely to be retained because they are e coated with gelatin. Pills can stick to a normal esophagus, especially when taken without water or by a patient in the supine position. Any area of the esophagus can be affected, although sites of natural compression may be more susceptible. Sustained-release compounds may be more damaging than standard preparations. Injury can range from minor irritation to frank ulceration, hemorrhage and, ultimately, stricture formation. Some of the more common offending medications include antibiotics (especially the tetracycline family) and antivirals, aspirin and other nonsteroidal antiinflammatory drugs (NSAIDs), potassium chloride, quinidine, ferrous sulfate, alendronate, and pamidronate.

Radiation-Induced Esophagitis

Patients undergoing radiation treatment for underlying malignancy may develop esophagitis. The degree of injury is related to the total dose of radiation received. The mucosa becomes inflamed and friable. Agents used during sclerotherapy can also cause esophagitis.

Clinical Features

Esophagitis, regardless of cause, usually manifests with dysphagia or odynophagia. Chest pain is frequently present, and esophageal bleeding can occur, ranging from localized oozing as a result of inflammation to frank hemorrhage. Ulceration and perforation can result in mediastinitis.

Gastroesophageal Reflux Disease

The most common clinical manifestation of GERD is heartburn, defined as a burning sensation that begins in the substernal area and radiates toward the neck. Reflux may also cause a dull discomfort, localized pressure, or severe squeezing pain across the middle of the chest. The patient may appear comfortable or may have associated diaphoresis, pallor, nausea, and vomiting, leading to the consideration of an ischemic cardiac syndrome. A detailed history is often helpful in differentiating cardiac chest pain from reflux, although the distinction may not be possible in the ED.

Other symptoms of GERD include regurgitation (spontaneous appearance of an acid or bitter material in the mouth or pharynx) and water brash (a vagally mediated hypersalivation response that may produce as much as 10 mL of saliva in 1 minute). Dysphagia and odynophagia may also be presenting complaints and may be associated with more serious complications.

Any condition or agent that decreases LES pressure, decreases esophageal motility, or prolongs gastric emptying predisposes patients to reflux (Box 79.2). Body positions that place the gut below the diaphragm increase the risk of reflux.

### BOX 79.2

**Agents and Conditions Related to Gastroesophageal Reflux**

**DECREASED LOWER ESOPHAGEAL SPHINCTER PRESSURE**
- Anticholinergic drugs
- Benzodiazepines
- Caffeine
- Calcium channel blockers
- Chocolate
- Estrogen
- Ethanol
- Fatty foods
- Nicotine
- Nitrates
- Peppermint
- Pregnancy
- Progesterone

**DECREASED ESOPHAGEAL MOTILITY**
- Achalasia
- Diabetes mellitus
- Scleroderma

**INCREASED GASTRIC EMPTYING TIME**
- Anticholinergic drugs
- Diabetic gastroparesis
- Gastric outlet obstruction
esophageal and cardiac chest pain. The occurrence of reflux after pain, location, or radiation. Radiation of pain can be a feature in emic coronary disease and GERD based only on features of the chest pain in adults. It is difficult to differentiate between ischemic and GERD as the cause.

If the refluxate reaches the proximal esophagus, otolarynologic manifestations may result, even in the absence of esophageal symptoms. Reflux can cause hoarseness, chronic laryngitis, refluxory sore throat, and globus sensation. Refluxate that enters the oropharynx may lead to gingivitis, halitosis, or dental problems, such as erosion of the lingual sides of the teeth as a result of acid exposure. Otalgia and hiccups can also result from reflux.

Eosinophilic Esophagitis

The most common symptom of eosinophilic esophagitis in adults is solid food dysphagia. In addition to dysphagia, patient may presents with nausea and vomiting, food impaction, and/or heartburn. Children may present with more vague symptoms, such as vomiting, regurgitation, nausea, epigastric or abdominal pain, chest pain, water brash, and globus sensation. Children with eosinophilic esophagitis have a higher rate of atopy, immunoglobulin E (IgE)–mediated food allergies, and family history of allergies. This diagnosis should be considered in patients who have severe GERD symptoms despite the use of acid suppression medications and in patients with chronic unexplained dysphagia or recurrent esophageal food impaction. The diagnosis is confirmed by biopsy during endoscopy.

Infectious Esophagitis

Infectious esophagitis usually causes severe odynophagia. Dysphagia of solids and liquids may be present. Pain may be so severe that the patient refuses to eat or drink. Heartburn and nausea may be presenting symptoms, but the pain is not improved by antacid therapy. Immunocompromised patients may have fever or bleeding, without dysphagia or odynophagia. Many patients with esophageal candidiasis also have oral candidiasis but it is possible only to have esophageal manifestations, which makes it more difficult to diagnose.

Pill Esophagitis

Patients with pill esophagitis commonly present with chest pain (72%), odynophagia (39%), and dysphagia (30%). Most patients have no prior history of esophageal disease and experience sudden onset of pain worsened by swallowing. Dysphagia may be present. Although some patients complain that a pill has become stuck, the history of pill ingestion can be difficult to obtain because symptoms may begin hours after the offending pill was taken. Atypical presentations include a burning type of pain, suggesting GERD as the cause.

Differential Diagnosis

Acute cardiac ischemia should be considered as a possible cause of chest pain in adults. It is difficult to differentiate between ischemic coronary disease and GERD based only on features of the pain, location, or radiation. Radiation of pain can be a feature in esophageal and cardiac chest pain. The occurrence of reflux after meals is another important feature in the history. A feeling of fullness after meals occurs commonly in reflux and is helpful in differentiating it from coronary artery disease.

Relief of chest pain from reflux by antacids is a key point in the history; however, one should not place too much weight on this point as evidence against a cardiac cause. The relief is often short-lived, and pain may recur in a short time. Esophageal pain may be provoked by swallowing. Other GI disorders such as gastritis, esophagitis, peptic ulcer disease (PUD), and biliary tract disease should be considered in the differential diagnosis.

Diagnostic Testing

GERD is a common problem, and additional diagnostic testing in the ED is rarely necessary, assuming that other, more serious causes of the patient’s symptoms have been excluded. Patients with dysphagia, odynophagia, or bleeding should be referred for further study.

Endoscopy can be used to evaluate pathologic changes, but there is no direct correlation between symptoms and endoscopic features. With infectious esophagitis, direct visualization may reveal characteristic signs of infection, such as white plaques of Candida or herpetic vesicles. Definitive diagnosis can be made through brushings and biopsies. Radiographic studies are usually not helpful because the findings are nonspecific.

Management

Gastric Reflux

Lifestyle modification solely as an initial approach to GERD has little therapeutic benefit without concomitant medical management. Lifestyle modifications to reduce GERD symptoms include avoidance of foods that can precipitate reflux (eg, caffeine, alcohol, chocolate, fatty foods) and avoidance of acidic foods that can cause heartburn (eg, citrus products, spicy foods). In addition to these dietary changes, other behavioral modifications include weight loss, smoking cessation, elevation of the head of the bed, and avoidance of a recumbent position for several hours after eating. The only lifestyle recommendations that have evidence-based support are weight loss and head of bed elevation; however, others can be useful adjuncts in select patients.

The pharmacologic therapy of GERD includes agents that neutralize acids, decrease acid production, act on the LES or affect motility, and protect the mucosa. The most effective treatment for GERD is reduction of acid production. Many patients self-medicate with antacids, over-the-counter (OTC) type 2 histamine receptor (H₂)–receptor antagonists, or PPIs. A Cochrane systematic review has concluded that PPIs are more effective than H₂ blockers in eliminating symptoms and healing mucosal damage. However, H₂ blockers are an acceptable alternative for patients with mild to moderate GERD. These agents do not stop the reflux but reduce the potency of the refluxate. Choices of H₂ blockers and PPIs are listed in Tables 79.1 and 79.2. All these agents are generally regarded as safe and effective.

Another agent that may be of benefit in refractory cases of symptomatic esophageal reflux is sucralfate, which can be used with other agents such as PPIs and H₂ blockers. The dose is 1 g every 6 hours. Sucralfate is a mucosal protectant that binds to inflamed tissue to create a protective barrier. It blocks the diffusion of gastric acid and pepsin across esophageal mucosa and can limit the erosive action of pepsin and bile. It has limited side effects and can be safely used in pregnant women.

Prokinetic agents treat GERD by increasing LES pressure. They may also be used for patients whose symptoms suggest a superimposed motility disturbance (eg, regurgitation, choking, abdominal distention). In addition to improving the propulsive activity...
of the stomach and small and large intestines, the increase in esophageal peristalsis and LES tone is an effective therapy for reflux by improving the clearance of refluxate. Metoclopramide (10-mg dose) may be used for these patients, but its efficacy has not been conclusively demonstrated, and it can cause significant irreversible extrapyramidal side effects such as tardive dyskinesia.

Patients with clinically suggested GERD who do not improve with empirical therapy and those who are at high risk for complications should be referred to a gastroenterologist for confirmation of the diagnosis and follow-up care. In these cases, further diagnostic evaluation may be necessary. Patients who are intolerant of acid-suppressive medications may be candidates for surgical therapy with laparoscopic fundoplication. Less invasive endoscopic therapies include thermal ablation to narrow the esophagus at the LES, suturing to create a plication at the LES, and injection therapy with laparoscopic fundoplication. Less invasive endoscopic therapies include thermal ablation to narrow the esophagus at the LES, suturing to create a plication at the LES, and injection therapy with laparoscopic fundoplication. Less invasive endoscopic therapies include thermal ablation to narrow the esophagus at the LES, suturing to create a plication at the LES, and injection therapy with laparoscopic fundoplication.

**Eosinophilic Esophagitis**

These patients usually are seen after standard antireflux measures have failed or they have developed a food impaction. Once food impaction is eliminated as the presenting problem, empirical treatment by initiation of a daily PPI and referral to a gastroenterologist for urgent endoscopy is recommended. Untreated eosinophilic esophagitis can lead to esophageal remodeling and stricture formation in up to 40% of adult patients. Although consensus has not yet been reached regarding an optimal treatment regimen, success has been reported with the use of topical (ie, swallowed) corticosteroids. Pediatric studies have also shown efficacy of the use of oral viscous budesonide.

**Infectious Esophagitis**

For infectious esophagitis, therapy is directed at the causative organism. Patients with normal immune systems and mild cases of oropharyngeal candidiasis can be treated with clotrimazole troches (10 mg dissolved in the mouth, five times daily for 1 week) or nystatin (400,000–600,000 million units orally [PO] four to five times/day for 2 weeks). Patients with true esophageal candidiasis should be treated with fluconazole (400 mg as a loading dose and then 100–400 mg daily for 14 to 21 days). In patients unable to tolerate oral medication, fluconazole can be given by the IV route.

Herpes esophagitis is generally a self-limited process that resolves within 1 to 2 weeks. Immuno-compromised patients should be treated with antivirals, such as acyclovir (400 mg PO, five times/day for 7–14 days, or 5–10 mg/kg IV tid for 7–14 days), famciclovir (500 mg PO, tid for 7–14 days), or valacyclovir (1 g tid for 7–14 days). For CMV, initial treatment can begin with ganciclovir (5 mg/kg IV bid for 2–3 weeks) or foscarnet (60 mg/kg IV tid or 90 mg/kg IV bid for 2–3 weeks).

**Pill Esophagitis**

If a patient with suspected pill esophagitis has persistent symptoms, endoscopy may be necessary. It also helps determine alternative causes. No data supports a specific treatment although, intuitively, antacid medication may prevent further erosion of damaged mucosa. Symptoms may take up to 6 weeks to resolve.

The best treatment for pill esophagitis is prevention. Patients should be instructed to drink at least 4 ounces of liquid with any pill. All medications should be taken when the patient is in an upright position, and he or she should remain upright for several minutes after medication ingestion. Patients with underlying esophageal abnormalities or who are bedridden should avoid the use of pills whenever practical.

**Disposition**

Treatment of esophagitis is largely symptom-based and supportive. Patients who cannot eat or drink because of injury to the esophagus should be admitted for IV fluid therapy. Treatment of GERD is directed at symptom management. GERD can be safely managed on an outpatient basis but ED disposition decisions are largely based on the ability to rule out other more serious causes of the patient’s complaints, such as ischemic coronary disease. For infectious esophagitis, if the causative organism cannot be identified or the patient is severely debilitated, hospitalization may be required. In addition to therapy directed at the infecting organism, treatment with antacids, topical anesthetics, or sucralfate may provide symptomatic relief.

Patients discharged from the ED should receive appropriate follow-up with the relevant specialist (eg, gastroenterology, infectious disease).

**GASTRITIS AND PEPTIC ULCER DISEASE**

**Principles**

**Background**

Gastritis and PUD are often difficult to differentiate based on history alone. Strictly speaking, gastritis is a histologic diagnosis denoting inflammation of the gastric mucosa. Hence, the
diagnosis of gastritis can be made only by endoscopy and biopsy. However, it is common practice for clinicians to use the term gastritis to refer to symptoms of dyspepsia. To confuse the picture further, gastroenterologists frequently use the term to refer to the endoscopic finding of an edematous friable mucosa. However, without accompanying inflammation, this is more appropriately termed gastropathy rather than gastritis. This section considers gastritis and gastropathy together as one entity because the distinction has little importance to emergency care. Gastric and duodenal ulcers are usually grouped together as PUD because of the similarity in their pathogenesis and treatment.

Pathophysiology

The most common cause of gastritis is infection with Helicobacter pylori. Although most patients are asymptomatic at the time of initial exposure, acute infection with H. pylori can cause severe gastritis and PUD. The identification of H. pylori has dramatically shifted our notion of PUD from an acid-related to an infectious disease-mediated process.

H. pylori is a spiral, flagellated, gram-negative rod whose natural habitat is the human stomach, between the epithelial cell surface and overlying mucus. It is estimated that 70% to 80% of patients with duodenal ulcer and 60% to 70% of patients with gastric ulcer are infected with H. pylori. It is more prevalent in lower socioeconomic groups and in developing countries. It is probably spread by person to person by an oral-oral route, although the fecal-oral route and iatrogenic transmissions have also been hypothesized.

It is estimated that up to 40% of the US population is infected with H. pylori. It is found in people of all age groups, although infection is typically acquired during childhood. Its presence is believed to cause mucosal inflammation that disrupts the normal defense mechanisms and leads to ulceration. It also increases the risk of gastric carcinoma and, less often, lymphoma. Although there is a strong association between H. pylori and PUD, only 5% to 10% of infected patients develop ulcers. It is unclear what role environmental and host factors (eg, diet) play. It is now accepted that almost all non–NSAID-related ulcers are caused by H. pylori. Eradication of infection with H. pylori results in more rapid healing of ulcers, prevents relapse, and diminishes the rate of ulcer complications. It is also more cost-effective than chronic antisecretory therapy.

Suppurative gastritis, also known as acute phlegmonous gastritis, is a rare and often fatal disease that results from an acute bacterial infection of the stomach wall. Streptococcus bacteria species are involved in nearly 75% of all cases of suppurative gastritis. Patients usually have an underlying mucosal abnormality such as cancer, ulcer, or preexisting gastritis. Less common infectious causes of gastritis include mycobacterial, viral, parasitic, and fungal organisms.

Use of aspirin and other NSAIDs is the second most common cause of PUD. Up to 25% of chronic NSAID users develop ulcer disease, and 2% to 4% of these patients have serious complications, including perforation or bleeding. The cause of NSAID–related ulcers is suppression of gastric prostaglandin synthesis. Prostaglandins promote mucosal integrity by maintaining mucosal blood flow, promoting mucosal mucus and bicarbonate formation, and reducing mucosal acid secretion. It is believed that the inhibition of cyclooxygenase (COX) by NSAIDs leads to a diminished level of protective prostaglandins in the stomach. In addition, the antiplatelet aggregation effect of NSAIDs may increase the amount of bleeding associated with NSAID–induced ulcers.

NSAIDs differ in their ulcerogenic potential. Studies have shown a higher risk of upper GI bleeding with ketorolac and piroxicam, particularly if their use extends beyond 5 days. The

COX-2–specific inhibitors (eg, celecoxib, rofecoxib, valdecoxib) were initially thought to have a better GI safety profile than traditional NSAIDs. However, further studies have refuted this belief and noted an increased risk of cardiovascular side effects, including myocardial infarction and stroke. As a result, rofecoxib (Vioxx) and valdecoxib (Bextra) were withdrawn from the market. Celecoxib (Celebrex) is still available in the United States as a treatment for arthritis and familial polyposis but has a black box warning regarding an increased incidence of GI side effects and increased cardiovascular risk (Box 79.3).

Patients older than 60 years, those with a prior history of an ulcer or hemorrhage, those receiving higher doses of NSAIDs, and patients concurrently taking glucocorticoids or anticoagulants are at higher risk for NSAID-induced gastroduodenal toxicity. These patients should be considered for ulcer prophylaxis with a PPI or misoprostol.

Other drugs with ulcerogenic potential include 5-fluorouracil, mycophenolate mofetil, and the biphosphonates. Other drugs implicated in causing gastritis are potassium preparations and iron supplements. Gastritis can result from short- and long-term exposure to ethanol.

Any condition that causes hypovolemia or hypotension can lead to gastritis. Ulcer formation may ultimately result. This may be a major causative factor in the development of gastritis and upper GI bleeding in intensive care unit patients. Other causes of gastritis include radiation, autoimmune reactions, Crohn’s disease, and sarcoidosis.

Many mechanisms can protect the gastric mucosa from the digestive effects of the hydrochloric acid, proteolytic enzymes, bile, and other deleterious substances to which it is exposed. Normally, a gastric mucosal barrier to intraluminal gastric acid is present and prevents the back-diffusion of hydrogen ions from the gastric lumen. Sodium ions are prevented from moving in the opposite direction. This ionic impermeability protects the gastric mucosa from gastric secretion–induced damage. Damage to the gastric mucosal barrier from any cause (Box 79.4) allows hydrogen ions and digestive enzymes to make contact with the gastric mucosa, leading to inflammation, bleeding, and potential ulceration.

H. pylori infection and use of NSAIDs account for the vast majority of PUD cases. Only 1% of PUD is caused by acid hypersecretion. Zollinger-Ellison syndrome is an acid hypersecretion syndrome caused by increased levels of circulating gastrin from gastrin-secreting tumors. The gastrin produced stimulates the gastrin-secreting tumors. The gastrin produced stimulates the gastrin-secreting tumors. Thus these patients have increased parietal cell mass and hypersecretion of acid, leading to ulcer formation.

PUD also occurs in infants and children. Infants with PUD usually demonstrate poor feeding, vomiting, or failure to thrive.

Up to 25% of children have isolated hematemesis or melena as presenting signs. Toddlers and preschool children may have abdominal pain, vomiting, and bleeding. Of ulcers in this age group, 80% are stress ulcers associated with systemic illness such as sepsis, head trauma, burns, or sickle cell disease. Older children and adolescents usually have primary PUD, with presentations similar to those of adults.

Clinical Features

Acute gastritis and PUD may cause epigastric abdominal pain, nausea, and vomiting. By definition, gastritis or gastropathy cannot be diagnosed based on clinical features alone. However, a good clinical history such as recent NSAID use or alcohol ingestion in the setting of the epigastric burning pain supports a presumptive clinical diagnosis.

Patients with phlegmonous gastritis usually appear toxic. Patients with gastritis as a result of decreased mucosal blood flow may have symptoms of abdominal pain and upper GI bleeding in addition to those of their underlying disease. Complications of gastritis include perforation and gastric outlet obstruction.

The classic presenting symptom of PUD is epigastric pain described as burning or gnawing. However, up to 2% of patients with endoscopically proven PUD are asymptomatic. Patients may also have atypical symptoms, including pain in other areas of the abdomen, chest, or back, and may describe the pain as vague or crampy. Associated symptoms include fullness, nausea, early satiety, and bloating. Pain usually occurs 2 to 5 hours after a meal or at night. Symptoms that awaken a patient from sleep between midnight and 3 AM is a classic indicator of ulcer disease, because in most people gastric acid output is highest at about 2 AM. Ulcer pain is usually not present on awakening in the morning because gastric acid output is at its lowest at this time. Colicky pain is rarely gastric or duodenal in origin. Well-defined periods of exacerbation and remission are usually present with a duodenal ulcer and aid in the diagnosis. A constant pain lasting from weeks to months is uncommonly caused by ulcer disease. Relief of pain after eating is another feature of gastric or duodenal ulcer. The pain from a duodenal ulcer is usually worse immediately before a meal, and so-called pain-eating relief is typical.

Although some patients with ulcers may vomit, alternative diagnoses such as gastric volvulus, gastric outlet obstruction, small bowel obstruction, pancreatitis, or biliary tract disease should be considered in patients with epigastric pain and vomiting. Relief of abdominal pain with antacids is an important aspect of the history. Antacids usually afford relief of pain in PUD and gastritis. Of patients with PUD, 90% have pain relief with antacids, and 75% with gastritis have relief. Patients with duodenal ulcer usually experience pain relief within 5 minutes after taking an antacid.

Physical findings in patients with PUD are usually minimal. Mild epigastric tenderness may be elicited. A positive stool guaiac test may be evidence of a slowly bleeding ulcer, but other causes of occult bleeding should also be considered.

Complications

The most serious complications of PUD include hemorrhage, perforation, penetration, and gastric outlet obstruction. Hemorrhage is the most common complication, occurring in 15% to 20% of patients. Ulceration into an artery can lead to life-threatening hemorrhage. Patients older than 60 years are at greater risk. Approximately 2% to 10% of patients experience perforation, which occurs when an ulcer erodes through the wall and leaks air and digestive contents into the peritoneal cavity. Duodenal ulcers account for 60% of all perforations, followed by antral gastric ulcers (20%) and gastric body ulcers (20%). Penetration is pathologically similar to perforation, except that the ulcer erodes into another organ such as the liver (usually from a gastric ulcer) or pancreas (usually from a duodenal ulcer) instead of into the peritoneal cavity. Gastric outlet obstruction occurs in 2% of ulcer patients as a result of edema and scarring near the gastroesophageal junction. Symptoms may manifest as gastroesophageal reflux, early satiety, weight loss, abdominal pain, and vomiting.

Pain patterns may be helpful in diagnosing some of the complications of PUD. Pain from a perforated duodenal ulcer is usually appreciated first in the epigastrium but becomes generalized within a short time. Vomiting is present in 50% of patients, and peritoneal findings usually result. Pneumoperitoneum commonly occurs after duodenal ulcer perforation, and the accumulated air under the diaphragm may cause referred pain to the shoulder. One or both shoulders may be involved, depending on the location of the free air.

A history of ulcer-like anterior abdominal pain that begins to radiate into the back suggests penetration of a duodenal ulcer. The pain is usually described as steady and is perceived at the level of the lower thoracic and upper lumbar vertebrae. The pain becomes refractory to treatment with antacids and food. Also, the pain may radiate to the chest, right upper quadrant, and left upper quadrant in up to 20% of patients. The sudden onset of pain, especially if unrelated to eating, suggests ulcer perforation or gastric volvulus.

Differential Diagnosis

Many other disorders can produce epigastric pain that mimics the pain of gastritis or PUD. Before either of these diagnoses can be made, other diseases that cause nausea, vomiting, and upper abdominal pain should be excluded, such as pancreatitis, biliary tract disease, and small bowel obstruction. Esophageal disorders such as GERD, esophagitis, or esophageal spasm can arise with abdominal symptoms. Mesenteric ischemia should be considered, especially in older adults and those with underlying vascular disease or atrial fibrillation. The possibility of an ACS should also be considered.

It can be difficult to distinguish between gastritis and PUD. The discomfort associated with gastritis is often mild to moderate in severity and described as a hot burning pain or bloating. In particular, burning pain is twice as common in gastritis as in PUD.

Diagnostic Testing

Because the diagnosis of gastritis is made clinically, no specific diagnostic tests are necessary. Ancillary tests should be ordered as clinically indicated to rule out other possible diagnoses or assess for complications of gastritis, such as bleeding, obstruction, and perforation.
Upper endoscopy is the procedure of choice for confirming the diagnosis. This is not typically performed in the ED unless it is necessary to treat complications of PUD, such as acute bleeding.

Abdominal and chest radiographs should be ordered if obstruction, perforation, or penetration is suggested, or if a pulmonary cause is being considered, although negative radiographs do not definitively rule out these diagnoses. Electrocardiography should be performed in any patient thought to have a cardiac cause for the pain. A pregnancy test should be performed on any woman of childbearing age.

Patients can be tested for H. pylori by invasive and noninvasive methods. These include a urea breath test, serum antibody testing, stool antigen testing, and direct mucosal biopsy during endoscopy. None of these methods are currently practical to use in the ED.

Management

Therapy of presumptive gastritis should be directed toward treating the suggested underlying cause. Acid suppression may improve symptoms of dyspepsia in patients taking NSAIDs. Patients with persistent symptoms should be referred to a gastroenterologist for further diagnostic evaluation.

For NSAID-related ulcers, treatment should begin with discontinuation of the offending agent and initiation of a PPI. For ulcers not related to NSAIDs, it is recommended to treat for H. pylori infection.

Some recommended regimens combine antibiotics with acid-suppressing agents for treatment of H. pylori infection (Box 79.5). Commercially available combination products may also be prescribed that may assist in compliance (eg, Prevpac, which contains lansoprazole, amoxicillin, and clarithromycin, and Helidac, which contains bismuth subsalicylate, metronidazole, and tetracycline). Continued therapy with antisecretory agents after an antibiotic-containing regimen is recommended.

**Antacids**

By the time most patients seek treatment for upper GI complaints, they have already tried some form of antacid therapy because these agents are readily available as OTC preparations. Antacids afford pain relief for most patients with PUD. Doses with a low neutralizing capacity (as low as 30 mEq) promote ulcer healing. Antacids may also work by binding bile acids or inhibiting pepsin.

The choice of antacid should be individualized. The magnesium-containing antacids can produce diarrhea in up to 25% of patients. Magnesium-containing antacids can also lead to an increase in serum magnesium levels and should be avoided or used with caution in patients with impaired renal function. Aluminum-containing antacids may cause constipation, and prolonged use may lead to phosphate depletion. Calcium-containing antacids have been marketed as acid neutralizers and as a means of calcium supplementation, especially for postmenopausal women. Calcium-containing antacids have been traditionally believed to cause the highest incidence of acid rebound, a paradoxical increase in gastrin secretion and acid production. Calcium antacids can also lead to constipation, and their excess consumption can lead to hypercalcemia, alkalosis, and renal insufficiency—the milk-alkali syndrome.

Antacids can also decrease the absorption of warfarin, digoxin, some anticonvulsants, and some antibiotics. It is recommended that antacids be administered 1 to 3 hours after meals and at bedtime. Antacids are the least expensive drugs available to treat PUD, but their use is limited by efficacy, side effects, and inconvenient administration schedules.

**Histamine Blockers**

Histamine is the primary stimulus to gastric acid secretion. It binds to the histamine-2 (H2) receptor located on the basolateral portion of the parietal cell to stimulate the release of hydrochloric acid. The discovery of the ability of H2 blockers to inhibit gastric acid production was a major advance in antulcer therapy because ulcers cannot develop in the absence of acid. These drugs are highly selective competitive inhibitors of histamine for the H2 receptor on parietal cells and reduce the volume of gastric juice and its hydrogen ion concentration. All the currently available H2 blockers are rapidly absorbed after an oral dose, with peak levels reached within 1 to 2 hours. All have half-lives of approximately 2 to 3 hours, so their effects last for about 6 hours. Most are now available OTC in lower dosage strength.

H2 blockers are effective in treating duodenal ulcer and, to a lesser extent, gastric ulcer, although they are not as effective as the PPIs. They are widely prescribed for symptoms of dyspepsia and work well in patients with episodic heartburn. All H2 blockers are mainly metabolized hepatically and renally, with the exception of nizatidine, which is almost exclusively metabolized renally. Dosages of all these agents should be reduced in patients with renal failure.

H2 blockers are safe and generally well tolerated. Side effects are rare but include central nervous system effects, such as somnolence, dizziness, and confusion. Transient increases in liver enzyme levels may be noted. Some patients may exhibit abnormalities in cardiac conduction because there are H2 receptors in the heart. Cimetidine has been shown to cause gynecomastia. Dosages of the various agents are summarized in Table 79.1.

**Proton Pump Inhibitors**

The H+-K+-ATPase (proton pump) is located on the apical portion of the parietal cell and is responsible for the production of hydrogen ions in gastric acid. PPIs are the most potent inhibitors of gastric acid secretion. They work by irreversibly binding to

PO, Orally; PPI, proton pump inhibitor.

stimulated proton pumps to block the secretion of hydrogen ions. Although they have no effect on the volume of gastric juice produced, production of acid can be reduced by up to 95%. Both basal and stimulated gastric acid secretions are reduced. The anti-secretory effects last up to 72 hours.

PPIs should be administered before the first meal of the day because the number of proton pumps is maximized after a fasting state. At the cellular level, additional proton pumps are continuously recruited to produce more acid in response to stimulation; therefore, several doses of a PPI are necessary for the maximal antacid effect to be achieved. The use of these medications on an as-needed basis would not be expected to provide a good clinical response; H₂ blockers are more suitable for this purpose.

PPIs are heptatically metabolized, and dosage should be modified in patients with hepatic failure. Side effects are usually minimal, and the long-term safety of these drugs has been shown in multiple studies. PPIs may be used at significantly higher dosages in patients with Zollinger-Ellison syndrome. Dosages of the various agents are summarized in Table 79.2. Lansoprazole, pantoprazole, and esomeprazole are available as IV formulations.

PPIs have been linked to inhibition of the effects of thiopropyrindines used to treat cardiovascular disease. Laboratory studies have shown a decrease in the inhibition of platelet aggregation when clopidogrel (Plavix) was combined with PPIs in healthy subjects. Retrospective observational studies have also suggested a potential increase of re-infarction and hospitalization when clopidogrel was used in combination with PPIs. The mechanism hypothesized is a competitive inhibition of the cytochrome P450 isozyme (CYP2C19), which converts clopidogrel to an active state. Two prospective randomized control trials have been performed, but both failed to show an increased cardiovascular risk for patients using both clopidogrel and PPIs. Overall, the data are mixed, and further research is needed to determine if there is an important clinical effect on patients taking both clopidogrel and PPIs. At this time, we recommend using PPIs and clopidogrel with caution and only when the benefits of PPIs outweigh the potential risks.

Prostaglandins

Prostaglandins exert protective effects on the gastric mucosa by inhibiting acid secretion and decreasing the amount of cyclic adenosine monophosphate generated in response to histamine. Inhibition of gastric acid secretion, increased secretion of mucus and bicarbonate, and stimulation of mucosal blood flow have all been demonstrated. Misoprostol is an analogue of prostaglandin E₁, with a longer duration of action and greater potency than endogenous prostaglandins. It should be used only for the prevention of NSAID-induced gastric ulcers in patients at high risk. The dose is 200 µg qid with food, but crampy abdominal pain and diarrhea may necessitate the use of a somewhat less effective dose of 100 µg qid. Misoprostol is an abortifacient and therefore is contraindicated in any female patient of childbearing age who is not using contraception.

Other Agents

Sucralfate binds to epithelial cells and especially to ulcerated surfaces, providing a protective layer that inhibits further acid damage. Its mechanism of action is not completely understood, although it has been shown to enhance epithelial growth, suppress acid secretion, and inhibit the growth of H. pylori. The usual dose is 1 g qid given 30 to 60 minutes before meals, and it can be used to complement other medications.

Bismuth compounds such as bismuth subsalicylate decrease pepsin activity, increase mucus secretion, and form a barrier to further acid damage in ulcer craters. They also increase prostaglandin synthesis and retard hydrogen ion diffusion through the mucosal barrier. Bismuth may also help heal ulcers through its bactericidal action on H. pylori. Bismuth compounds are not approved for the treatment of peptic ulcers.

Disposition

Referral to a gastroenterologist is suggested if any of the following signs or symptoms are present: age 55 years or older with new-onset dyspepsia, dysphagia, progressive unintentional weight loss, persistent vomiting, iron deficiency anemia, or an epigastric mass. Most patients with PUD can be safely managed as outpatients, with referral to gastroenterology for confirmation of diagnosis with an extraglottic device (EGD). Further evaluation is required for patients with high-risk clinical features (eg, anemia, report of GI bleeding, intractable pain, signs of gastric obstruction) prior to discharge.

GASTRIC VOLVULUS

Principles

Gastric volvulus is a rare cause of severe abdominal pain that occurs when the stomach rotates on itself more than 180 degrees, creating a closed loop obstruction. It is a rare condition whose true incidence is unknown because some types of volvulus are intermittent and resolve spontaneously. Gastric volvulus may be classified according to cause (primary vs. secondary), anatomy (axis of rotation), or onset (acute vs. chronic).

The stomach is fixed at only two points, the esophagocardiac junction and pylorus. The remainder of the organ is relatively distensible and mobile and can occupy various positions within the abdomen. When a person is supine, the stomach lies entirely above the umbilicus, whereas it descends below the umbilicus when a person is in the erect position. Regardless of its position, the stomach maintains its familiar morphology because of ligamentous attachments to the surrounding organs. A primary (or subdiaphragmatic) volvulus occurs when the stabilizing ligaments are too lax or are congenitally abnormal in such a way that the stomach is able to twist on itself. Approximately one-third of cases are of this type.

Secondary (or supradiaphragmatic) volvulus occurs in patients with diaphragmatic defects such as a paraesophageal hiatal hernia, elevated diaphragm, gastric ulcer or carcinoma, diaphragmatic paralysis, extrinsic pressure on the stomach from other organs, or abdominal adhesions. The combination of one of these factors and ligamentous laxity makes a volvulus more likely.

Gastric volvulus can also be classified on the basis of its axis of rotation. The most common form is organoaxial volvulus, which occurs when the stomach twists on its long axis. Less commonly, the stomach folds on its short axis from its lesser to greater curvature and is classified as a mesenteroaxial volvulus. Approximately one-third of cases of gastric volvulus are of this type.

Clinical Features

Gastric volvulus usually occurs in persons 40 to 50 years of age and is typically associated with the presence of a paraesophageal hernia. Approximately 20% of cases occur in infants younger than 1 year, often associated with a congenital diaphragmatic defect.

The presenting features of a gastric volvulus vary, depending on the type. Primary volvulus may arise with the sudden onset of severe abdominal pain. The upper abdomen may demonstrate...
marked distention. Patients with secondary volvulus may experience predominant symptoms in the chest, with pain radiating to the back and shoulders, along with accompanying dyspnea. The abdominal examination may be unremarkable. Nonbilious vomiting is usually present and may be persistent and severe. The combination of severe epigastric pain and distention, vomiting followed by violent nonproductive retching, and inability to pass a nasogastric tube (Borchardt’s triad) increases the likelihood of a gastric volvulus. Up to 25% of children with acute gastric volvulus present with life-threatening events that necessitate resuscitation, including apnea, cyanosis, and acute respiratory distress.

A volvulus may be chronic if the rotation is minimal, and there is no vascular compromise. Symptoms usually consist of mild intermittent upper abdominal pain. Early satiety, dyspnea, bloating, eructation, and upper abdominal fullness may be present. It is unknown how often a chronic volvulus can lead to an acute volvulus.

**Complications**

If an acute volvulus is not identified and corrected early, it may lead to gastric ischemia, perforation, and death. The mortality rate from acute gastric volvulus has been reported to be as high as 50%. Fortunately, the frequency of gastric infarction is low (reportedly 5% to 28% for organoaxial volvulus) because of the redundant blood supply of the stomach. Other complications include ulceration, perforation, hemorrhage, pancreatic necrosis, and omental avulsion.

**Differential Diagnosis**

The differential diagnosis of gastric volvulus includes any disease that can arise with sudden upper abdominal pain and vomiting. Perforated peptic ulcer, gastric outlet obstruction, biliary tract disease, and acute pancreatitis should be considered. Symptoms of a volvulus may suggest those of an ACS.

**Diagnostic Testing**

A plain abdominal radiograph often demonstrates a large, gas-filled loop of bowel in the abdomen or chest16 (Fig. 79.4). A barium swallow may help visualize the abnormality, and CT can be used for confirmation in equivocal cases. There are no laboratory findings specific for volvulus, although elevations in amylase and alkaline phosphatase levels have been reported.

**Management**

The goal of treatment of an acute gastric volvulus is reduction. Mortality rates increase with delayed diagnosis because of ischemic complications. Acutely, one should attempt passage of a nasogastric tube, which may occasionally reduce the volvulus. Although somewhat controversial, patients without signs of gastric infarction may undergo an attempt at endoscopic reduction. Ultimately, treatment is a surgical emergency, with the goal of reducing the volvulus and preventing recurrence by fixing the stomach within the abdomen. Surgical repair of predisposing diaphragmatic defects is also recommended to prevent recurrence.

**Disposition**

Patients with an acute gastric volvulus require admission and surgical consultation due to the high morbidity and mortality associated with the condition.

CHAPTER 79: QUESTIONS & ANSWERS

79.1. What is an appropriate first-line treatment regimen for H. pylori infection?
A. Bismuth subsalicylate, ranitidine, and clarithromycin
B. Metronidazole and sucralfate
C. Omeprazole, amoxicillin, and clarithromycin
D. Omeprazole and bismuth subsalicylate
E. Ranitidine, omeprazole, and amoxicillin

Answer: C. The recommended triple-treatment regimen for H. pylori infection is a PPI (eg, omeprazole, 20 mg bid), amoxicillin (1 g bid) and clarithromycin (500 mg bid) for 14 days. Quadruple therapy with Pepto Bismol, metronidazole, tetracycline, and a PPI-ranitidine is an alternative option. See Box 79.5.

79.2. What percentage of esophageal foreign bodies require an intervention (usually nonoperative) for removal?
A. <10%
B. 10%–20%
C. 20%–30%
D. 30%–40%
E. >40%

Answer: B. Most foreign bodies pass spontaneously. Approximately 10%–20% require intervention, but less than 1% require surgery for removal.

79.3. A 5-year-old child is brought to the ED by his mother after a possible ingestion of a plastic Lego piece. He has had no pulmonary symptoms but reports difficulty swallowing and declines to drink liquids that are offered. What would be the intervention of choice?
A. Contrast-enhanced CT scan of the chest
B. Endoscopy
C. Non–water-soluble barium swallow
D. Posteroanterior and lateral chest radiography
E. Water-soluble barium swallow

Answer: B. Because the patient is symptomatic, endoscopy is indicated. A CT scan of the chest is useful for organic and inorganic materials. A basic chest radiograph cannot reliably exclude a foreign body. Barium swallow is difficult in pediatric patients, particularly this child, who is refusing oral fluids. Water-soluble media risk pneumonitis if aspirated. Non–water-soluble materials risk increased inflammation if leakage occurs into the mediastinum. Barium may also obscure subsequent endoscopic visualization.

79.4. Which of the following statements regarding the pharmacologic treatment of an esophageal obstruction from a food bolus is true?
A. Carbonated beverages are a safe and useful adjunct at any point.
B. Glucagon has the additional benefit of moderate antiemetic properties.
C. Glucagon has been proven to help facilitate passage of a food bolus anywhere in the esophagus.
D. Glucagon is contraindicated with sharp-edged foreign bodies.
E. Papain (meat tenderizer) can be used to soften a food bolus and help with passage.

Answer: D. Glucagon is a smooth muscle relaxant, so it is theoretically useful only for distal esophageal foreign bodies. There are only anecdotal reports of success with glucagon, but no randomized controlled trials have shown a statistical benefit over placebo. There are many adverse effects, including flushing, nausea, and vomiting, that can potentially increase the risk of aspiration. It is contraindicated for use with sharp or damaging foreign bodies. There is only low-level evidence to support the use of effervescent agents, and they are relatively contraindicated after 24 hours because of perforation concerns. The use of meat tenderizer (papain) should be avoided because it can significantly worsen inflamed mucosa and increase the risk of perforation.

79.5. Which of the following is an indication for urgent esophagoscopy?
A. Button battery in the stomach
B. Chest pain due to foreign body
C. Coin in the proximal esophagus
D. Nausea and vomiting
E. Object failing to pass out of the esophagus after 12 hours

Answer: C. A coin that remains lodged in the proximal esophagus should be removed. Other indications are inability to handle secretions, sharp objects, esophageal button battery (alkaline) in the esophagus, and impactions that fail to pass after 24 hours.

79.6. By the age of 50 years, what percentage of the population has endoscopic evidence of gastritis?
A. 10%
B. 20%
C. 30%
D. 40%
E. 50%

Answer: E.

79.7. A 32-year-old otherwise healthy man presents with acute onset of epigastric pain radiating to his chest that woke him from sleep at 2 AM. It was a burning pain associated with water brash. There were no associated pulmonary symptoms. His past medical history is negative except for tobacco use and heartburn. His electrocardiogram is normal and his upright chest radiograph is also normal. Vital signs and physical examination findings are unremarkable. He is currently pain-free. His troponin...
level is normal. What would be the most appropriate intervention?
A. Cardiology consultation for catheterization
B. Contrast-enhanced CT scan of the chest
C. Discharge on aspirin, 325 mg once daily
D. Serial troponins
E. Trial of twice-daily proton pump inhibitors

Answer: E. Peak gastric acid secretion occurs during the early morning hours between 1 a.m. and 3 a.m., with a typical scenario of being awakened from sleep. The shared afferent neural pathway makes the pain of gastroesophageal reflux disease (GERD) often similar to that of pain of cardiac origin. Gastric acid secretion is lowest at approximately 6 A.M, so awakening in the morning with pain from GERD is unusual.

79.8. A 45-year-old woman presents several hours after an upper endoscopy with severe chest pain and neck discomfort. She is awake and alert, but rates pain as 10 of 10. What is the most appropriate test to confirm the diagnosis?
A. Abdominal x-ray
B. Barium contrast esophagography
C. Gastrografin (water-soluble) contrast esophagography
D. Ultrasound
E. Upper endoscopy

Answer: C. We recommend an initial attempt with a water-soluble agent in patients who are awake and alert and are not at risk for aspiration. Barium sulfate is superior for identifying small perforations; however, it may incite an inflammatory response in tissue and should only be used if no initial perforation is identified with water-soluble contrast. Endoscopy is generally not recommended except in cases of penetrating trauma because insufflation could potentially enlarge a minimal transmural opening.
HEPATIC DISORDERS

HEPATITIS

Hepatitis is a generic term referring to inflammation of the liver. It is usually a consequence of a viral infection or alcohol abuse (see below). However, it is important to remember that hepatitis can be caused by other infections (eg, bacterial, fungal, or parasitic) and other toxic exposures (eg, industrial chemicals, prescribed medications, nutritional supplements), as well as by immunologic disorders.

Viral Hepatitis

Principles

Many viruses are associated with some degree of measurable liver inflammation. However the most significant and potentially severe cases of viral hepatitis are caused by type A (infectious), type B (serum), type C (posttransfusion), and delta viruses. The Epstein-Barr virus, the causative agent of mononucleosis, is also a common cause of hepatitis, although it is more important clinically for its nonhepatic effects.

Hepatitis A. Hepatitis A virus (HAV), is an RNA enteroviral picornavirus. It is spread by the fecal-oral route directly or through contaminated water or foodstuffs. Transmission by blood is a theoretic possibility but is exceedingly rare. HAV can occur sporadically but is notorious for its association with epidemics generally linked to common source outbreaks. HAV infection is common worldwide; serologic evidence of previous infection exists in nearly 100% of the adult population in some regions. In the United States, close to 50% of all urban-dwelling adults are seropositive for antibody for HAV. High rates of seropositivity in association with the relatively small number of reported episodes support the notion that many cases may be asymptomatic. Occult disease appears to be more common in children, and 70% of those infected may be asymptomatic. Routine vaccination of children is recommended, which has contributed to a profound shift in reported new cases to adults—specifically, men who have sex with men (MSM), illicit intravenous drug users (IVDUs), and non–injection drug users (Fig. 80.1). The most common risk factor for hepatitis A in persons older than 15 years is travel outside of the United States.

The incubation period for hepatitis A ranges from 15 to 45 days (typically, 30 days), with a relatively short duration of viremia that is most prominent before the onset of symptoms. Fecal shedding and maximum infectivity occur before the onset of symptomatic disease and generally have waned by the time jaundice appears (Fig. 80.2). HAV is not associated with a chronic carrier state.

Hepatitis B. Hepatitis B virus (HBV) is contained in a 42-nm structure called the Dane particle. Within this enveloped virion are the viral DNA, DNA polymerase, hepatitis B surface antigen (HBsAg), and hepatitis B core antigen (HBcAg). Hepatitis Be antigen (HBeAg) is an immunologically distinct antigen not incorporated into virions; instead, it is secreted from cells into the serum of infected patients. In contrast to HAV, for which there is only a single antigenic variety, several genotypes of HBV, as defined by surface antigen, are recognized. HBV is transmitted principally by parenteral exposure but also can be transmitted through intimate contact. The highest rates of infection are among IVDUs and homosexual men. Transmission by blood transfusion, previously a common source of infection, has been eliminated because of modern blood bank screening techniques. Similar to HAV, the incidence of hepatitis B has continued to decline (Fig.80.3).

HBsAg has been detected in a variety of bodily secretions, including saliva, semen, stool, tears, urine, and vaginal secretions. Although the presence of HBsAg is not synonymous with infectivity, HBV DNA has been identified in several of these fluids and is likely to be infectious. The typical interval between exposure and onset of clinical illness is 60 to 90 days; however, serologic markers of infection generally appear within 1 to 3 weeks (Fig. 80.4). Approximately 10% of adults and 90% of infected neonates with immature immune systems will become asymptomatic chronic carriers of HBsAg. Health care workers who routinely come into contact with blood have a prevalence of HBsAg of 1% to 2%, and 15% to 30% show serologic evidence of previous infection. Among emergency clinicians, seropositivity rates of 12% and 15% have been reported. The likelihood of becoming chronically infected with HBV varies inversely with the age at which infection occurs. This age-dependent relationship is believed to be related to the protective abilities of gut microbiota, which are known to increase with age. HBV transmitted from HBsAg-positive mothers to their newborns results in HBV carriage in up to 90% of infants, whereas only 6% to 10% of acutely infected adults become carriers. In general, less than 5% of hepatitis B infections in healthy immunocompetent adults will progress to chronic hepatitis.

Chronic hepatitis is usually defined as the presence of HBsAg in serum for longer than 6 months, serum HBV DNA level greater than 20,000 IU/mL (105 copies/mL; lower values are often seen in HBeAg-negative chronic hepatitis B), persistent or intermittent elevation in alanine aminotransferase (ALT) and aspartate aminotransferase (AST) levels, and a liver biopsy showing chronic hepatitis with moderate or severe necroinflammation.

Hepatitis C and E. What was historically termed non-A, non-B hepatitis is caused by at least two distinct RNA viruses, hepatitis C virus (HCV) and hepatitis E virus. In the United States, hepatitis C infection is currently the leading cause of cirrhosis. Before widespread blood supply screening, hepatitis C was commonly transmitted through blood transfusions and organ transplantation in the United States. With the 1992 implementation of screening donor blood for surrogate markers (aminotransferases) and antibody to hepatitis C, and nucleic acid amplification testing, the hepatitis C transmission risk from blood transfusion has been reduced to approximately 1 in 1 million (0.0001%)/units transfused. The strongest risk factors for HCV infection are a history
of IVDU, having had 20 or more lifetime sex partners, and having undergone blood transfusions before 1992. Among patients infected with human immunodeficiency virus (HIV), the incidence of coinfection with hepatitis C is 15% to 30%. This rate approaches 50% to 90% in those who acquired HIV through IVDU. Patients coinfected with HIV and HCV generally have a more aggressive course of both infections. In 40% to 57% of cases of hepatitis C, no source of infection is identified. The incubation period for hepatitis C is 30 to 90 days (mean, 50 days). Following the incubation period, a self-limited acute phase begins. The acute phase is asymptomatic in up to 70% of individuals with hepatitis C. This phase persists for up to 12 weeks and is rarely associated with hepatic failure. Approximately 90% of HCV infections progress to chronic hepatitis. Long-term follow-up studies during a period of approximately 20 years postseroconversion have indicated that clinical liver disease develops in only 10% to 20% of those infected. In the United States, it has been estimated that 4.1 million persons are infected with HCV, and 3.2 million persons have chronic hepatitis C infection. Unlike HAV and HBV, HCV incidence has continued to increase (Fig. 80.5). Hepatitis C seroprevalence among persons born between 1945 and 1965 (baby boomers) presenting to the emergency department (ED) has been documented to be 11%, or one in every nine emergency visits in this age group. This alarming disease prevalence, coupled with decreased disease awareness among health-despaired populations, has been prompting a push for ED screening.

**Hepatitis D.** Hepatitis delta virus (HDV) was discovered in 1977 in liver specimens from patients with chronic HBV infection. It is a defective RNA virus that can infect only patients who are actively producing HBsAg, which is required for its viral coating.
In the United States, the incidence of HDV antibody is 4% to 30% of patients with chronic HBV infection. As a consequence of the routine association with chronic HBV infection, it is likely that many cases of HDV infection are misdiagnosed as acute or reactivated hepatitis B.

HDV is spread in a manner similar to that of hepatitis B, being most common among IVDUs, promiscuous homosexual men, and patients with hemophilia. Infection with HDV can occur concomitantly with HBV (coinfection) or subsequent to earlier HBV infection (superinfection), because HDV cannot replicate in the absence of HBV. Cases of superinfection may present as acute self-limited disease to fulminant hepatitis or chronic infection. Fulminant hepatitis is more often observed with HBV-HDV coinfection than with HBV monoinfection.

Hepatitis E and G. Hepatitis E, which is associated with fecal-oral transmission, is encountered most often in Asia, Africa, and Russia. Hepatitis E has an incubation period of 15 to 60 days. Hepatitis G virus (HGV), also referred to as hepatitis GB virus type C, is the most recently identified cause of viral hepatitis. It is an RNA virus that is transmitted through blood transfusion, parenteral exposure to blood products, and possibly during intimate sexual contact. The virus has been identified in patients with acute and chronic hepatitis. It is believed to be an innocent bystander, with disease manifestations attributable to coinfection with another hepatitis virus.

Clinical Features
The clinical presentation of viral hepatitis is highly variable, with a significant number of those infected being asymptomatic. The most common symptoms and signs are malaise, fever, and anorexia, followed by nausea, vomiting, abdominal discomfort, and diarrhea. The first prompt to seek medical care is typically jaundice. A small number of patients with hepatitis B may experience a prodromal illness characterized by arthralgia, arthritis, and dermatitis. The joint involvement typically is polyarticular; the small joints of the hands and wrists are usually affected. Joint fluid usually is noninflammatory, with cell counts as high as 90,000/mm. The characteristic dermatitis is urticarial but may be macular, papular, or petechial.

Fulminant hepatitis is characterized by an acute onset that progresses to hepatic failure and encephalopathy over a period of days characterized by altered mentation and spontaneous mucosal bleeding. Although most often encountered with HBV and HDV coinfection, fulminant hepatitis can occur in association with all the causative viruses (1% to 2% of all cases).

Physical findings include elevated temperature, scleral or cutaneous icterus, and abdominal tenderness. There may be vomiting resulting in tachycardia and supine or orthostatic hypotension. Hepatomegaly may occur and is characterized by a smooth, homogeneous, tender liver surface. Even if liver enlargement is not appreciated, tenderness to percussion over the lower right ribs may be present. Scleral icterus is generally noticeable earlier than cutaneous discoloration. Muddy sclera, commonly found among African American patients, may obscure or confuse this finding; sublingual or subungual surfaces are alternative sites to examine. Scleral icterus usually occurs once the serum bilirubin level is above 2.5 mg/dL. Spider angioma and splenomegaly, although usually associated with cirrhosis, may be features in acute presentations. Gray or acholic stools are distinctly uncommon.

Differential Diagnosis
The protean nature of the symptoms and signs associated with viral hepatitis makes the differential diagnosis of this disorder quite broad in scope. Beyond a variety of nonhepatic viral illnesses, all the infectious, chemical, and immunologic causes of hepatic inflammation must be considered, in addition to biliary tract disease. A viral cause is often suggested by the medical history, but serologic tests are required for confirmation. Alcoholic hepatitis is associated with a history of chronic or excessive alcohol consumption, less marked elevation of hepatic transaminase levels, and AST levels elevated above those of ALT. Extrahepatic obstruction, cholecystitis, and cholelithiasis are excluded by their lack of association with significant elevation of aminotransferase levels; abdominal ultrasound imaging or abdominal computed tomography (CT) may be required to exclude these other diseases.

Diagnostic Testing
Laboratory tests are critically important in diagnosing hepatitis and determining the specific cause. The most useful tests are measurements of the hepatic aminotransferase and bilirubin levels. Typically, hepatitis is associated with elevations (10- to 100-fold) of serum AST and ALT levels, with the ALT level generally elevated in excess of AST. The bilirubin level may be moderately increased (5–10 mg/dL), and occasionally is markedly elevated (15–25 mg/dL). Hyperbilirubinemia typically emerges several days to 1 week or more after the onset of clinical symptoms. Direct and indirect bilirubin levels are elevated almost equal proportions. Alkaline phosphatase and lactate dehydrogenase levels may be elevated but are rarely more than 2 to 3 times normal.

The prothrombin time (PT) or international normalized ratio (INR) is useful in assessing the degree of hepatic synthetic dysfucntion. Elevation of the PT or INR may be the first clue to a complicated course. The white blood cell (WBC) count generally is not useful in the diagnosis because values range from low overall counts with a lymphocytic predominance to marked polymorphonuclear leukocytosis. Although determining the precise cause of hepatitis can rarely be achieved in the ED, serologic testing should be initiated as soon as possible (Table 80.1) because they affect prognosis and public health issues.

Acute hepatitis A is diagnosed by the presence of immunoglobulin M (IgM) HAV antibody, whereas previous infection is determined by detection of an IgG antibody. Acute hepatitis B is characterized by the presence of HBsAg and IgM antibody to HBcAg. HBsAg alone does not establish the diagnosis of acute hepatitis B because it can be absent late in the course of acute disease or present chronically. Anti-HBc antibody generally is the best indicator of previous HBV infection, whereas anti-HBsAg antibody is the best marker for immunity to HBV. Figs. 80.2 and 80.4 show the temporal relationships among infection, clinical
symptoms, and serologic responses for the two most common causes of viral hepatitis, HAV and HBV.

Due to its prolonged incubation period, early diagnosis of hepatitis C is based on the exposure history and elimination of other causes. Screening is done by serologic detection of hepatitis C antibodies. Confirmation by a polymerase chain reaction (PCR) assay that detects HCV RNA facilitates a definitive diagnosis. There can be a delay between the onset of symptoms and development of assayable antibody. Furthermore, the HCV antibody test does not distinguish acute from chronic infection. Repeat PCR testing at 6 weeks may establish acute versus chronic hepatitis. Variable low levels of HCV RNA suggest acute infection, whereas nonvariable, higher HCV RNA levels are more consistent with chronic hepatitis C infection. Also, the presence of hepatic fibrosis assessed by histologic analysis (from biopsy) or noninvasive serum and ultrasonographic testing can establish that a chronic state is present.

Due to coinfectivity, diagnosing HDV infection with a serologic test for the antibody to HDV (anti-HDV) requires a thorough testing approach because it may be mistaken for acute or chronic HBV infection. The presence of anti-HDV in conjunction with IgM antibody to HBcAg suggests coinfection with HDV and HBV. Anti-HDV in association with IgG antibody to HBcAg supports the diagnosis of superinfection.

Management

Most patients with viral hepatitis have self-limited disease, with asymptomatic and histologic resolution in 2 to 4 weeks. ED management is primarily symptomatic. It often is necessary to correct fluid and electrolyte imbalances secondary to poor oral intake or excessive diarrhea or vomiting. Antiemetics may allow resumption of adequate oral intake, thereby avoiding the need for hospitalization. In the anorexic or nauseated patient, fluid intake should be encouraged, with avoidance of solids until they are palatable. Medications requiring a primarily hepatic metabolism do not need to be discontinued nor the dosage adjusted unless there is significant hepatic dysfunction, as indicated by elevated serum aminotransferase and bilirubin levels, encephalopathy, or rising PT or INR. Nonessential drugs with hepatotoxic potential should be avoided. Alcohol consumption should be completely discontinued until signs of liver injury have disappeared. Due to the lack of evidence, we do not recommend a role for corticosteroids in the treatment of hepatitis.

Complications of acute hepatitis are usually related to fluid or electrolyte imbalance as a result of inadequate oral intake or refractory emesis. Severe vomiting can result in upper gastrointestinal (GI) bleeding from an esophageal tear. The most severe complication of acute disease is the development of liver failure, heralded by hepatic encephalopathy.

Although hepatitis A is self-limited and does not progress to a chronic state, isolation, handwashing, and attention to hygienic practices should be undertaken to prevent spread of infection. Patients are contagious during the incubation period and remain contagious until 1 week after the appearance of jaundice.

Prevention and Postexposure Management. Effective preexposure and postexposure prophylaxis for HAV and HBV has been available for more than 2 decades. Passive immunization with immune globulin plays a role in overall disease prevention and should be used to treat nonimmunized individuals exposed to HBV. To be effective in prophylactic prevention, serum immune globulin must be administered within 2 weeks of exposure. However, due to cost, self-limited nature of the disease, and transmission risks inherent to the pooled, blood-derived source of hepatitis A immune globulin, its use is reserved for immune-naïve individuals who are at increased risk from hepatitis A exposure or those who are allergic to the vaccination for hepatitis A.

Emergency health care workers are at increased risk for exposure to all types of hepatitis because of frequent contact with bodily fluids, blood, and interaction with high-risk patients. Historically, the seropositivity rate among ED nurses is 30% and 12% to 15% among ED physicians. Markers for hepatitis C were identified in 18% of patients in an inner city ED; the potential associated health risk to staff is unknown.

All ED personnel involved in patient care or custodial work should be vaccinated for HAV and HBV before or soon after starting employment. The vaccines are highly effective and are associated with minimal acute or delayed toxicity. A complete three-injection series of vaccine—to the deltoid for optimal immunologic response—produces protective antibody in approximately 95% of persons. Hepatitis B immune globulin (HBIG) is recommended for immediate passive immunization of those not previously immunized who have been exposed to potentially infectious material. Immune globulin diminishes the risk of HBV infection by 75%. Unvaccinated exposed people should receive HBIG, 0.06 mL/kg intramuscularly (IM), in addition to the HBV vaccine. Fig. 80.6 outlines an approach for managing health care.

CHAPTER 80 Disorders of the Liver and Biliary Tract

Fig. 80.6. Management of health care workers exposed to blood or other infectious secretions. HB, Hepatitis B; HBIG, HB immune globulin; HBcAb, hepatitis B core antibody; HBsAb, hepatitis B surface antibody; HBsAg, hepatitis B surface antigen; IM, intramuscularly.

1High risk defined as exposure to patient in one of the following groups: homosexual men, intravenous drug users, recent immigrants from endemic region.

2HBIG – 0.06 mL/kg IM, as soon after exposure as possible, no later than 7 days past exposure.

3HB vaccine – 1 mL IM deltoid, refer for completion of series to include three injections total, test for response within 60 days of last vaccination.
workers exposed to blood or other potentially infectious secretions. A safe and effective vaccine for HAV is available; however, health care workers are currently not on the list for recommended routine immunization.

The risk of seroconversion after percutaneous exposure from an HCV-positive source is approximately 1.8%. Despite the theoretic risk of blood-borne HCV exposure among health care workers (HCWs), the prevalence of HCV infection in this group is approximately the same as in the general population. No effective vaccine for HCV is currently available. Previously, it was thought that the use of peginterferon alfa-2b may decrease seroconversion in HCWs exposed to blood from HCV-infected individuals. However, already low transmission rates, coupled with no additional benefit of prophylactically treated over untreated HCWs, has resulted in no accepted preexposure or postexposure prophylaxis regimen for HCV. Recent success in the use of direct-acting antiviral agents (eg, sirineprevir, sofosbuvir, ledipasvir) has led many to consider a future role for these agents in postexposure prophylaxis.11 Universal precautions—the use of gloves, masks, protective eyewear, and gowns—constitute the first and best means of defense for persons who work in proximity to potentially infective bodily fluids.

Disposition

Hospitalization is rarely required for the management of viral hepatitis and generally is reserved for the patient with a fluid and electrolyte imbalance or refractory vomiting. Patients with less severe illness may require hospitalization for concomitant medical problems or if suitable living arrangements are not available. Altered sensorium, a PT more than 3 seconds, or an INR more than 1.5 may suggest fulminant disease or an increased likelihood of a complicated course, necessitating hospitalization for observation. The emergence of fulminant disease should lead to consideration of transfer to a facility that can offer liver transplantation.

Treatment of chronic hepatitis C is a rapidly evolving area of medicine. Current therapy involves genotype-specific, direct-acting antiviral (DAA) regimens using nucleoside polymerase inhibitors (eg, sirineprevir, sofosbuvir, ledipasvir). The goal end point is a sustained virologic response (SVR) defined as absence of HCV RNA by PCR testing 3 to 6 months after stopping treatment.12 Referral to a hepatocellular carcinoma.

Principles

Alcoholic Hepatitis

Alcohol-related liver disease accounts for just under 1% of world-wide mortality.15 Alcohol and its metabolites are toxic to most organ systems and are largely eliminated by metabolic degradation in the liver; up to 15% of alcohol is excreted unchanged in the urine or expired air. The precise pathogenesis of alcoholic liver disease is unknown and probably is multifactorial. Probable causal factors include coexistent malnutrition, accumulation of toxic metabolites (eg, acetdehyde), depletion of glutathione, abnormal metabolism of methionine, excessive production of nicotinamide adenine dinucleotide (NADH), induction of microsomal enzymes as a result of the metabolism of alcohol, and alteration of immune function.14

Although susceptibility to liver damage varies based on genetic heterogeneity, a rough correlation is recognized between the amount of ethanol ingested and risk of developing liver disease. The risk of liver injury increases as daily consumption exceeds 80 g of ethanol daily in men and 20 g in women. For men, this is equivalent to a six-pack of beer, four to six glasses of wine, or three to four mixed drinks daily. Fatty infiltration appears to depend on the duration and amount of alcohol consumed and, in general, is reversible when the patient stops drinking.

The most common variety of alcohol-induced liver disease is steatosis. Fatty infiltration of the liver is most likely a consequence of altered fatty acid metabolism resulting from a diminished NAD+/NADH ratio, which favors triglyceride production. Beyond enlargement of the liver, which usually is painless, this tends to be a benign process.

As alcohol-related liver disease progresses beyond steatosis, fibrosis, cirrhosis and finally hepatocellular carcinoma may ensue (Fig. 80.7). In more than 90% of those who regularly consume alcohol, steatosis can be seen as early as 2 weeks. Within 5 years, 8% to 20% of those with steatosis of the liver progress to having cirrhosis. Comorbidities that contribute to the progression of disease include viral hepatitis, HIV, and hemochromatosis. Approximately 3% to 10% of chronic alcoholics will develop hepatocellular carcinoma.

Clinical Features

Alcoholic hepatitis is a potentially severe form of alcohol-induced liver disease. Most cases probably are subclinical, but the spectrum of presentation can range from nausea, vomiting, and abdominal pain to acute liver failure. Physical findings include tachycardia, fever, and supine or orthostatic hypotension. Abdominal tenderness usually can be elicited, especially in the right upper quadrant. Coexistent fatty infiltration may produce palpable hepatomegaly; cirrhosis from chronic disease may result in a small nonpalpable liver. The characteristic physical signs of cirrhosis may be present—gynecomastia, spider angiomata, muscle wasting, ascites, and palmar erythema. Jaundice can be noted in patients with a bilirubin level of at least 2.5 mg/dL. As disease advances, peripheral edema, abdominal distention, hematemesis, and melena may be present. Patients with clinical signs of alcoholic hepatitis should be assessed for symptoms of gastritis and GI bleeding.

Differential Diagnosis

The differential diagnosis of alcoholic hepatitis is broad in scope and includes many other alcohol-related GI maladies (eg, gastritis,
Laboratory tests reveal moderate elevations of AST and ALT levels. Values in excess of 10 times normal are unusual, even in severe cases associated with eventual liver failure. Compared with viral hepatitis, a relative predominance of AST to ALT is expected. The bilirubin level is commonly elevated, and the WBC count often is high, in the range of 10,000 to 20,000/mm. The PT and INR provide a rough assessment of hepatic dysfunction. An acutely pancreatitis). Initially, all the potential causative disorders must be considered; however, the clinical history and aminotransferase profile should facilitate accurate diagnosis. Mild aminotransferase level elevation and marked bilirubin level elevation are consistent with alcoholic hepatitis; ultrasonography will differentiate this from common duct obstruction. Serum should be sent for testing for anti-HAV IgM and hepatitis B core antibody (HBC Ab) IgM, but results usually are not available to establish these diagnoses in the ED.

**Diagnostic Testing**

Laboratory tests reveal moderate elevations of AST and ALT levels. Values in excess of 10 times normal are unusual, even in severe cases associated with eventual liver failure. Compared with viral hepatitis, a relative predominance of AST to ALT is expected. The bilirubin level is commonly elevated, and the WBC count often is high, in the range of 10,000 to 20,000/mm. The PT and INR provide a rough assessment of hepatic dysfunction. An acutely

- HIV

Alcoholic hepatitis

**Management**

The management of alcoholic hepatitis is principally supportive. Fluid and electrolyte imbalances must be corrected, usually requiring parenteral fluid replacement; antiemetics may mitigate the need for IV treatment. Alcohol may suppress gluconeogenesis, thereby causing hypoglycemia. The blood glucose level should be measured and supplemented, as indicated. Many alcoholics are malnourished and, if thiamine deficiency is suspected, thiamine should be given at a dose of 100 mg IV. Ethanol-induced magnesium wasting may not be apparent on serum magnesium measurement, and replacement should be given empirically unless the patient has a contraindication, such as renal failure or known hypermagnesemia. Magnesium can be given as the sulfate salt in a dose of 1 g IV or IM or as an oxide, chloride salt, or amino acid conjugate for oral replacement therapy at a daily dose of 200 to 1000 mg.

The overall nutritional status of the patient should be addressed with the administration of a high-calorie, vitamin-supplemented diet. Protein content may require restriction if evidence of cirrhosis is present. Existing gastritis should be treated with histamine H2 antagonists, proton pump inhibitors, and antacids. Variceal bleeding is associated with a 5-year mortality rate of 65%; acute bleeds require pharmacologic intervention that decreases portal blood flow, such as octreotide (50-µg bolus followed by 25–50 µg/h), somatostatin (250-µg bolus and 250 µg/h infusion), or vasopressin (0.4-unit bolus followed by 0.4–1 unit/min continuous infusion).15 Treatment should not be delayed while identification of the source of bleeding is undertaken. Varices that continue to bleed will require balloon tamponade. If rebleeding occurs, treatment options include endoscopic variceal ligation, endoscopic varical sclerotherapy, transjugular intrahepatic portosystemic shunt (TIPS), or surgical shunt placement.

The American Association for the Study of Liver Disease (AASLD) has recommended that treatment be based on the assessment of disease severity. There are several severity scales. The most widely used is the Maddrey discriminant function (MDF) score based on coagulation and bilirubin levels. Severe alcoholic hepatitis is indicated by an mDF score more than 32. In the absence of GI bleeding, hepatorenal syndrome, or sepsis, the American Association for the Study of Liver Disease (AASLD) recommends the initiation of corticosteroids (oral prednisolone, 40 mg daily, or parenteral methylprednisolone, 32 mg daily) for those with alcoholic hepatitis and an mDF score more than 32.15 Pentoxifylline, an inhibitor of cytokines such as anti–tumor necrosis factor alpha, has been shown to provide mild benefit over placebo and may be used to treat those with contraindications to corticosteroids.15 Compared to corticosteroids for the treatment of alcoholic hepatitis, pentoxifylline does not demonstrate improved 28-day survival.

**Disposition**

The disposition is determined by the patient’s clinical state—degree of fluid and electrolyte abnormality, ability to retain oral intake, any coexistent illnesses or complications—and socioeconomic circumstances. Hospitalization generally is not required. All patients should be advised to abstain from further alcohol ingestion and should be provided referral for detoxification or alcohol dependency treatment.

**CIRRHOSIS**

**Principles**

*Cirrhosis* is a generic term for end-stage chronic liver disease characterized by the destruction of hepatocytes and replacement of normal hepatic architecture with fibrotic tissue and regenerative nodules. Laennec’s cirrhosis is a diffuse process that involves the entire lobule, and 10% to 20% of chronic alcoholics develop this disorder. Postnecrotic cirrhosis usually is nonhomogeneous, characterized by regions of fibrosis and hepatocyte loss alternating with normal areas. It most often is a consequence of chronic hepatitis of various causes—infectious (viral, bacterial, fungal), drug-induced, or metabolic. Biliary cirrhosis is much less common and is a consequence of chronic extrahepatic biliary obstruction or is a primary disorder of autoimmune-mediated intrahepatic duct inflammation and scarring. Nonalcoholic fatty liver disease has become an increasingly recognized cause of cryptogenic cirrhosis. This still poorly understood disease, with features similar to those of Laennec’s cirrhosis, is more common in obese patients and those with type 2 diabetes mellitus.

**Clinical Features**

The clinical manifestations of cirrhosis are related to loss of hepatocytes, leading to metabolic and synthetic dysfunction, or to fibrosis and altered hepatic architecture, resulting in impaired...
portal vein blood flow and portal hypertension. Typically, the patient with cirrhosis complains of chronic fatigue and poor appetite. With the exception of those with biliary cirrhosis, many patients with cirrhosis can be asymptomatic until complications develop, such as GI bleeding, ascites, or hepatic encephalopathy. Patients with biliary cirrhosis generally complain of pruritus or exhibit obvious jaundice before end-stage cirrhosis or complications develop. Primary biliary cirrhosis may be associated with other immune-mediated disorders; these patients may have signs and symptoms characteristic of scleroderma or the CREST syndrome (calcinosis cutis, Raynaud’s phenomenon, esophageal motility disorder, sclerodactyly, and telangiectasia).

Physical examination may reveal muscle wasting, thinning of the skin with patchy ecchymosis, spider angiomata, palmar erythema, Dupuytren’s contracture and, in men, gynecomastia or testicular atrophy. Jaundice generally is absent in mild cases or in those with early disease. The liver may not be palpable if it is extensively scarred, but a large regenerative nodule, tumor, or fatty infiltration can result in hepatomegaly. Complications of cirrhosis include ascites, hepatic encephalopathy, and variceal hemorrhage. Ascites is the most common of these, particularly in those with advanced disease, and may be present with abdominal wall vein distention known as caput medusa.

### Diagnostic Testing

Laboratory tests are not specific. Aminotransferase levels are rarely more than minimally elevated. The bilirubin level may be increased but usually not until cirrhosis is far advanced. Elevation of the alkaline phosphatase level out of proportion to other liver enzyme levels is suggestive of biliary cirrhosis. Coagulation studies commonly show abnormalities, and the serum albumin level is low as a result of impaired hepatic synthetic function. Mild to moderate anemia and thrombocytopenia often are present in Laennec’s cirrhosis. An elevated blood urea nitrogen (BUN) or creatinine level suggests dehydration or hepatorenal syndrome. Ascites can be detected on a carefully performed physical examination or ultrasound. Bedside ultrasound demonstrating a diffuse nodular surface, with or without the presence of ascites, is consistent with cirrhosis (Fig. 80.8).

In patients with ascites and fever or abdominal pain, paracentesis should be considered to rule out spontaneous bacterial peritonitis (SBP). Nuclear scintigraphy or computed tomography (CT) imaging may reveal a hepatic or splenic appearance characteristic of cirrhosis and portal hypertension but, in general, these tests should be deferred to an elective setting.

### Management

Treatment of cirrhosis in the ED is limited in the absence of acute complications. Fluid and electrolyte imbalances should be corrected and vitamin and nutritional supplements provided. Most patients can be discharged with referral to a general internist for further evaluation and treatment.

The complications of cirrhosis include ascites with or without infection, GI bleeding, hepatorenal syndrome, and encephalopathy, discussed in the following section.

### Ascites

Ascites occurs as a consequence of portal hypertension, impaired hepatic lymph flow, hypoalbuminemia, and renal salt retention. When severe, it can cause respiratory compromise or significant discomfort. The treatment is paracentesis with removal of 2 L of fluid or more. Removal of very large quantities of ascitic fluid can result in body fluid and electrolyte abnormalities, intravascular volume depletion, and hemodynamic instability, commonly known as paracentesis-induced circulatory dysfunction. When removing over 5 L of ascitic fluid via paracentesis, colloid infusion is necessary to avoid adverse cardiovascular, renal, and neurohumeral responses. Standard dosing of albumin after large-volume paracentesis is 8 g/L removed. Studies evaluating the use of half-dose albumin (4 g/L) for large-volume paracentesis have been promising. The AASLD has established guidelines for the management of ascites secondary to cirrhosis (Table 80.3).

A low-sodium diet of less than 2000 mg of sodium, in conjunction with an aldosterone antagonist such as spironolactone 100 mg daily, may be of use in the chronic management of ascites. A low-dose regimen of a thiazide or loop diuretic (furosemide, 40 mg daily) may accelerate resolution of ascites and is probably safe if the patient has coexistent peripheral edema and normal renal function. Furosemide should be given orally because IV dosing can result in a decline in renal function. The presence of peripheral edema allows the rate of fluid removal to be faster than removal in those with only ascites. To avoid brisk intravascular volume depletion and azotemia when using diuretics to mobilize fluids, individuals with ascites without peripheral edema should not exceed 500 mL of fluid removal/day.

### Gastrointestinal Bleeding

Chapter 27 discusses the management of GI bleeding. In patients with cirrhosis, GI bleeding is often related to esophageal or gastric varices, but over 50% of cases result from some other source (e.g., gastritis, duodenal ulcer). Coagulopathy and thrombocytopenia in conjunction with active bleeding should be corrected with platelet transfusion. The goal should be to correct the platelet count to greater than 50,000/mm³. There is little support for the use of fresh-frozen plasma to correct asymptomatic abnormalities in PT and INR. Cryoprecipitate (1 unit/10 kg body weight) with a targeted fibrinogen level of more than 100 mg/dL may be used in active bleeding. Cryoprecipitate improves coagulopathies using a lower volume than fresh-frozen plasma. With uncomplicated prolongation of PT or INR in individuals with nutritional or gastrointestinal losses, treatment with oral vitamin K supplementation (10–20 mEq given bid to qid) may be used. If a patient has active bleeding, IV potassium (10 mEq per hour) may be substituted.

Mean arterial pressure (MAP) is an independent predictor of mortality in patients with cirrhosis. Lowering pressure may adversely affect survival. Angiotensin-converting enzyme (ACE)
Hepatorenal Syndrome

Hepatorenal syndrome (HRS) is defined as renal failure occurring in the setting of cirrhosis without obvious renal pathology. An elevated creatinine or blood urea nitrogen (BUN) level may herald the onset of hepatorenal syndrome and necessitates hospitalization of the patient for optimal fluid and electrolyte management. There are two classifications, type I HRS and type II HRS. Type I is the more severe and is associated with serum creatinine levels exceeding 2.5 mg/dL. Clinical recommendations summarized by the AASLD are outlined in Table 80.3. Despite the use of albumin and vasoactive medications such as norepinephrine to increase the MAP, hepatorenal syndrome carries a high mortality.

**HEPATIC ENCEPHALOPATHY**

**Principles**

Hepatic encephalopathy is a clinical state of altered cerebral function resulting from the diseased liver’s failure to perform its normal metabolic functions adequately. Ammonia, formed primarily in the GI tract by bacteria, is normally absorbed and converted to urea in the liver. In severe hepatic disease, ammonia accumulates, crosses the blood-brain barrier, and combines sequentially with α-ketoglutarate and glutamate to form glutamine. Serum ammonia levels correlate inconsistently with the severity of encephalopathy, but there is an association of ammonia levels with cerebrospinal fluid (CSF) glutamine levels. Whether glutamine is itself toxic or simply represents a marker for disordered central nervous system (CNS) metabolism is unknown.

**Clinical Features**

The clinical manifestations of hepatic encephalopathy range from mild cognitive dysfunction, irritability, and confusion to profound coma. Asterixis, a low-amplitude, alternating flexion and extension of the wrist that occurs when the wrist is held in extension, is characteristic of the neuromuscular dysfunction seen in mild to moderate degrees of encephalopathy. A similar finding may be elicited in the dorsi flexed foot or with extension of the neck. Fetor hepaticus, a musty breath odor presumably from mercaptans, may be detected in severe cases. Physical examination commonly reveals signs of cirrhosis—spider angioma, testicular atrophy, muscle wasting, superficial bruising, gynecomastia, and ascites.

**Differential Diagnosis**

The differential considerations in patients with suspected hepatic encephalopathy include all causes of altered sensorium. The scope of the differential diagnosis can be narrowed if the patient’s

*Type I hepatorenal syndrome (HRS).

inhibitors, angiotensin receptor blockers (ARBs), and beta blockers, such as propranolol, should be used with caution.
Diagnostic Testing

Liver function tests, including albumin and coagulation studies are recommended, although the results may be normal. Serum ammonia levels generally are elevated but do not necessarily correlate with the severity of encephalopathy. Results of tests reflective of hepatic synthetic function (ie, serum albumin, PT) are generally abnormal. Evaluation for underlying treatable causes (Box 80.1) is imperative. Serum chemistry tests to evaluate electrolyte and metabolic derangements as well as α-fetoprotein may reveal precipitating factors.

The presence of hypoalbuminemia must be considered in patients who require medications with high protein-binding profiles. The resultant decrease in protein binding and increased volume of distribution exposes the patient to potential drug toxicity. Drugs circulating in the extracellular compartment carry the greatest risk. Some commonly prescribed drugs with high protein-binding profiles include phenytoin, morphine, and antimicrobials. Additional dosing consideration should be given to agents that normally undergo hepatic metabolism with large first-pass extraction. With decreased hepatic flow and shunting, these agents are more apt to increase their bioavailability and serum concentrations. Finally, glutathione reduction and decreased renal elimination, which are commonly present in cirrhosis, may predispose individuals to further toxicity and liver injury, necessitating dosing adjustments by the treating emergency clinician.

Management

Aggressive management of the patient with hepatic encephalopathy may reverse the condition. As with any comatose patient, the airway is assessed first, not only to determine the need for respiratory support but also to prevent aspiration. Affected patients generally are hemodynamically stable but have an increased incidence of GI bleeding. Hypokalemia, alkalosis, and GI bleeding contribute to increased ammonia production or absorption, and the cause must be addressed when any of these abnormalities are detected. Relatively mild degrees of hyponatremia, hypoglycemia, azotemia, or dehydration often will have a disproportionate effect on cerebral function and require immediate correction. All CNS depressants and mild sedatives should be discontinued.

The current standard of care for patients with hepatic encephalopathy is treatment with nonabsorbable disaccharides (eg, lactitol, lactulose). Lactulose decreases the absorption of ammonia through its osmotic cathartic effects and by altering the colonic pH to trap ammonia as ammonium in the stool. The usual dose of lactulose is 30 to 60 g daily or in a quantity sufficient to result in several loose bowel movements daily. The principal adverse effect is excessive diarrhea, with resultant fluid and electrolyte imbalances.

Oral aminoglycoside antibiotics (eg, neomycin, vancomycin) as well as metronidazole have been effectively used with and without lactulose to reduce ammonia-producing enteric bacteria in patients with hepatic encephalopathy. Neomycin is a poorly absorbed aminoglycoside administered orally (PO) at an initial dose of 250 mg bid to qid (maximum, 4000 mg/day). In obtunded patients, lactulose and neomycin can be administered by nasogastric tube or rectal enema. Long-term use of aminoglycosides in patients with renal impairment or injury may result in nephrotoxicity and ototoxicity. Alternatively, rifaximin is a minimally absorbed, oral antimicrobial agent that concentrates in the GI tract. It offers minimal systemic bioavailability and fewer detrimental side effects than neomycin. It has equal or greater efficacy compared with other antibiotics used for hepatic encephalopathy and appears to have a lower bacterial resistance than systemic antibiotics. Glycerol phenylbutyrate may be added to a regimen of lactulose and rifaximin. Glycerol phenylbutyrate provides an alternative removal of nitrogen waste in the form of urinary phenylacetyl glutamine. The addition of glycerol phenylbutyrate to rifaximin lowers the number of hepatic encephalopathy events and decreases mean plasma ammonia levels.

Less commonly used in the United States, L-ornithine–L-aspartate (LOLA) has demonstrated benefit in lowering postprandial serum ammonia levels alone and following TIPS procedures (known to increase or exacerbate hepatic encephalopathy). It may be beneficial, even in patients with minimal hepatic encephalopathy. Complementary therapies include probiotics such as Lactobacillus acidophilus (to increase non–urease-producing bacteria), eradication of Helicobacter pylori (urease-producing), and zinc replacement (metabolism of ammonia is dependent on zinc and is deficient in liver disease).

Benzoate metabolizes ammonia by reacting with glycine. The benzodiazepine antagonist flumazenil, acarbose (inhibits upper GI tract carbohydrate conversion), and polyelectrolyte glycol (increases GI excretion) all have limited studies to support their use and require more investigation.

The molecular adsorbent recirculating system uses albumin in a dialysis solution to bind and remove circulating toxins. This novel experimental approach to treat liver failure and hepatic encephalopathy appears to be safe and cost-effective but, at present, is approved in the United States only for the treatment of liver failure resulting from a drug overdose or poisoning. Although it improves hepatic encephalopathy, studies have failed to demonstrate improved survival outcomes.

Constant daily management requires nutritional intake of 25 to 40 kcal/kg/day with dietary modification of protein. Protein intake should be approximately 1 to 1.5 g/kg/day. Because cirrhosis is commonly a comorbid condition associated with poor nutrition, protein should not be further restricted in patients with active hepatic encephalopathy.

Disposition

Although most patients with hepatic encephalopathy will require hospitalization, those with grade I or II encephalopathy without complicating factors and a supportive home environment can be managed on an outpatient basis. In addition to a prescription for lactulose and rifaximin, nutritional guidance to ensure adequate caloric intake and a maximum of 1.5 g/kg/day of protein is essential.

### BOX 80.1

**Underlying Causes of Hepatic Encephalopathy in Patients With Known Liver Disease**

- Gastrointestinal bleeding
- Electrolyte abnormalities including hypokalemia and alkalosis
- Venous thrombosis
- Ileus and constipation
- Sedative medications
- Dehydration and hypovolemia
- Acute or chronic kidney injury
- Infection
SPONTANEOUS BACTERIAL PERITONITIS

Principles

Spontaneous bacterial peritonitis is an acute bacterial infection of ascitic fluid in patients with liver disease, without an apparent external or intra-abdominal focus of infection. It can occur in any patient with ascites. Retrospective studies have identified SBP in up to 27% of patients hospitalized with cirrhosis and ascites.

The pathophysiology of SBP is related to a combination of impaired phagocytic function in the liver and to portal systemic hypertension, which can cause bowel mucosal edema, alterations in gut flora, and transmural migration of enteric organisms. Bacterial seeding may also occur from other sites in the abdomen, such as the bladder, as well as the lungs and blood. Gram-negative enteric organisms, primarily Escherichia coli and Klebsiella, are the most frequently identified organisms in SBP. Newer invasive treatments of cirrhosis, including variceal ligation, transjugular intrahepatic portosystemic shunt placement, and long-term antibiotic prophylaxis, have changed the type and cause of acute bacterial infections in cirrhosis. With improved cirrhosis care, the cause of outpatients with cirrhotic neutrocytic ascites has been found to be predominantly gram-positive. Polymicrobial and anaerobic infections have been reported but are not common.

Clinical Features

The clinical presentation of SBP ranges from acute onset of severe abdominal pain to slow insidious onset of abdominal discomfort to encephalopathy. Patients may have fever, although an elevated temperature is not always detected. Chills and hemodynamic instability may be slow to develop. On physical examination, palpation of the abdomen may elicit only mild tenderness or may reveal abdominal rigidity and guarding, with rebound tenderness. Although by definition ascites must be present for SBP to develop, free peritoneal fluid may not always be clinically apparent. One study has identified a positive peritoneal fluid culture rate of 3.5% among patients who were judged to have asymptomatic ascites. This observation underscores the exceptionally broad spectrum of manifestations and often very minimal physical findings with this disorder and indicates the need to consider the diagnosis of SBP in any patient with ascites who has abdominal pain or exhibits unexplained clinical deterioration.

Differential Diagnosis

The differential diagnosis for SBP includes all entities that may lead to peritonitis and abdominal pain in patients with or without liver disease.

Diagnostic Testing

Diagnosis is made by culture of the ascitic fluid, but treatment decisions should be made in advance of these results. An ascitic fluid granulocyte count greater than 500 cells/mm³ correlates with positive cultures in more than 90% of cases; however, ED treatment for SBP should be initiated if the neutrophil count is greater than 250 cells/mm³. Cultures of ascitic fluid guide the antibiotic choice. Also, fluid chemistry testing may aid in the diagnosis when the fluid neutrophil count is nondiagnostic or peritonitis secondary to another abdominal source (eg, urinary tract infection, appendicitis) is suspected. Determining protein, lactate dehydrogenase (LDH), glucose, carciinoembryonic antigen, and alkaline phosphatase levels and performing Gram staining to assist with the distinction of SBP from secondary peritonitis is recommended.

A positive result of ascitic fluid testing using leukocyte esterase reagent strips (LES) has a high degree of correlation with a clinically significant elevation of the neutrophil cell count in the fluid. Although not as sensitive as cultures, LES have been found to have a high specificity and moderate sensitivity, leading many to recommend their use for rapid testing and diagnosis of SBP.

Testing of ascitic fluid prior to administering antibiotics is imperative. A single dose of antibiotic will produce negative cultures at 6 hours in 86% of patients with SBP. Additional findings beyond an elevated neutrophil count include a pH of less than 7.34, pH gradient between the serum arterial blood and ascitic fluid of more than 0.1, or serum-ascites albumin fluid gradient (albumin in ascites subtracted from serum albumin level) more than 1.1 g/dL are early indicators of SBP.

Other laboratory parameters (eg, aminotransferase and bilirubin levels, peripheral blood count) are commonly abnormal, but such findings are nonspecific and more often are a consequence of underlying liver disease than infection. The PT and INR should be measured in advance of paracentesis, and fresh-frozen plasma should be administered if significant coagulopathy is identified.

Management

The treatment of SBP requires IV antibiotics. The choice of agents is driven by the anticipated bacteriology of the process. A third-generation cephalosporin, IV cefotaxime, 2 g every 8 hours, is considered to be the agent of choice. In patients capable of oral therapy without prior quinolone exposure, an alternative treatment is oral ofloxacin 400 mg bid. Ampicillin with an aminoglycoside is also effective but is associated with an increased risk of renal toxicity. Unless an atypical response, risk profile, or resistant organism is identified, patients with SBP should be treated for a total of 5 days.

Peritonitis is a frequent complication in patients undergoing peritoneal dialysis. Similar to peritonitis in cirrhosis, peritonitis in patients undergoing peritoneal dialysis may be spontaneous or secondary to underlying urinary tract, GI, or lung disorders. The most common symptoms include abdominal pain and cloudy peritoneal effluent. The diagnosis is presumed with a dialysate WBC more than 100 cells/mm³ and confirmed by culture. In patients with symptoms suggesting peritonitis, dialysate should be collected for analysis and culture, and treatment should be initiated. Consideration of catheter removal is also warranted. Intra-peritoneal antimicrobial administration is preferred over an IV regimen. The International Society for Peritoneal Dialysis guidelines recommend treatment that includes vancomycin or cefazolin, plus cefepime, ceftazidime, or aztreonam.

Disposition

Any patient with ascites is at risk for the development of SBP. This risk is markedly increased in patients with ascitic fluid protein levels less than 1 g/dL. Other important risk factors include serum bilirubin level greater than 3.2 mg/dL, platelet count less than 98,000/mm³, and a previous history of SBP. Antibiotic prophylaxis for high-risk patients can reduce SBP incidence by 60% to 80% and can be cost-effective. The preferred prophylaxis regimen consists of norfloxacin, 400 mg daily; additional regimens for prophylaxis include ciprofloxacin, 500 mg bid, or trimethoprim-sulfamethoxazole (TMP-SMX), 800/160 mg daily.

In patients with cirrhosis who are admitted for GI bleeding, prophylactic ceftriaxone (1 g daily) is used until the patient is taking food orally, at which time a switch to TMP-SMX should be undertaken.

Long-term outpatient prophylaxis with norfloxacin, ciprofloxacin, or TMP-SMX is recommended for patients who have survived an episode of SBP and those with higher risk ascitic fluid granulocyte counts.
laboratory values (protein < 1.5 g/dL, BUN level > 25 mg/dL, or serum sodium level < 130 mmol/L). If a high-risk patient with ascites is identified in the ED and contraindications are absent, prophylactic therapy should be initiated.

Finally, in patients with ascites secondary to cirrhosis, the prevention of SBP should also include consideration of discontinuation of proton pump inhibitors, which adversely alter acid secretion and gut flora, and beta blockers, which may increase risk secondary to their resultant systemic hypotension.

Patients with diagnosed SBP require hospitalization and will ultimately need a referral to a primary care physician or gastroenterologist for close outpatient follow-up. Most patients with SBP will not require repeat abdominal paracentesis. In those with inconsistent symptoms, abnormal treatment response, atypical organisms, or recent β-lactam exposure, repeat paracentesis may help differentiate secondary bacterial peritonitis requiring surgical interventions.

**HEPATIC ABSCESES**

Hepatic abscesses fall into two broad categories, pyogenic and amebic. Although there may be similarities in clinical presentation, the pathophysiology and treatment differ significantly.

**Pyogenic Abscess**

**Principles**

Liver abscesses are usually associated with biliary tract obstruction or cholangitis but may be related to diverticulitis, pancreatic abscess, omphalitis, appendicitis, inflammatory bowel disease, pneumonia, or bacteremia. Often, no underlying cause for hepatic abscess is identified. Solitary and multiple abscesses occur with approximately equal frequency, usually in the right lobe of the liver. Patients with multiple lesions tend to be more severely ill, with less favorable outcomes. Causative organisms may be anaerobic and aerobic; E. coli, Klebsiella, Pseudomonas, and Enterococcus spp., anaerobic streptococci, and various Bacteroides spp. are usually isolated.

**Clinical Features**

The clinical presentation is characterized by the onset of high fever, chills, right upper quadrant (RUQ) pain, nausea, and vomiting. Patients generally have an acute presentation and appear quite ill, particularly if there is underlying cholangitis. Physical findings include elevated temperature, RUQ tenderness, hepatomegaly, and occasionally dullness to percussion and decreased breath sounds over the right lower chest. Jaundice may be apparent, especially if coexistent biliary tract obstruction is present.

**Differential Diagnosis**

The differential diagnosis of pyogenic hepatic abscess includes amebic liver abscess, hepatitis, cholangitis, and pancreatic and subphrenic abscesses.

**Diagnostic Testing**

Laboratory findings include leukocytosis in 70% to 80% of cases, elevated alkaline phosphatase levels in up to 90%, and bilirubin level in excess of 2 mg/dL in 50% of patients. Although blood culture sensitivities are approximately 30% in patients with pyogenic abscesses, they should be determined in advance of treatment and while awaiting definitive drainage and testing from the abscess site. Serum aminotransferase levels commonly are elevated 2 to 4 times normal. Chest radiographs may reveal a right pleural effusion, basilar atelectasis, and/or an elevated right hemidiaphragm. The most useful, sensitive, and expeditious imaging modalities include ultrasonography and CT (Figs. 80.9 and 80.10).

**Management**

The initial treatment of a pyogenic hepatic abscess is hemodynamic stabilization, IV antibiotics, and pain control. Pending definitive microbial identification, broad-spectrum antibiotic coverage should be initiated and continued for 2 to 6 weeks, depending on the size of the abscess and patient response. Although there has been no consensus on treatment regimens, IV antibiotic coverage targeting gram-negative bacteria and anaerobes is recommended. This may include cefotaxime (2 g tid) plus metronidazole (500 mg tid) or ampicillin (2 g qid) in conjunction with gentamycin (1.7 mg/kg tid) and metronidazole or monotherapy with piperacillin-tazobactam (3.375 IV qid), imipenem, or meropenem. The addition of vancomycin is indicated for an acutely ill or unstable patient, as well as any patient with gram-positive cocci on staining or when suspicion for enterococcal or staphylococcal organisms is high. Fluoroquinolones, although often combined with metronidazole for continuation of treatment as an outpatient, should be avoided in areas with E. coli resistance greater than 10%.25
Definitive treatment for abscesses larger than 3 cm requires drainage. This usually is done percutaneously under image guidance, reserving open surgical drainage only for complex cases associated with intraperitoneal soiling, intestinal perforation, or biliary obstruction. Complications include rupture of the abscess into the peritoneal cavity or an adjacent anatomic structure (eg, thoracic cavity, lung, pericardium).

Disposition

Patients with pyogenic hepatic abscess require hospitalization. Consultation with a general surgeon, gastroenterologist, or interventional radiologist will be necessary.

Amebic Abscess

Principles

Amebiasis is one of the most common protozoal infections worldwide. Transmission generally occurs by the fecal-oral route, often as a consequence of ingesting contaminated water or foodstuffs. Although intestinal disease is by far the most common manifestation of infection, extraintestinal disease can occur, with the liver most commonly affected. *Entamoeba histolytica* is the only ameba responsible for invasive disease, and only certain varieties of *E. histolytica* are pathogenic after invasion of the intestinal mucosa and transit through the portal vein. As with a pyogenic abscess, involvement of the right liver lobe is more common.

Clinical Features

The clinical presentation generally is acute with fever, chills, nausea, vomiting, and abdominal pain. Diarrhea is common in children but is present in less than one-third of adults. Careful questioning of patients without diarrhea often yields a history of intestinal illness several weeks prior to presentation. Many patients complain of cough, which may direct attention away from the liver. A chronic illness of several months’ duration, although less common than the acute presentation, can occur. Physical findings include an elevated temperature, RUQ tenderness, hepatomegaly, and dullness, with decreased breath sounds over the right lower chest.

Differential Diagnosis

In order of their frequency of occurrence, the differential diagnosis includes pyogenic abscess, biliary tract disease, hepatitis, pneumonia, appendicitis, and pancreatitis. Respiratory symptoms and abnormalities on the chest radiograph may cause confusion with pulmonary illnesses. Hepatic imaging is helpful in establishing the diagnosis; however, differentiation from pyogenic illness is difficult and requires additional laboratory testing.

Diagnostic Testing

Laboratory findings in patients with an amebic abscess are not specific. Neutrophilic leukocytosis is common. The alkaline phosphatase level is elevated in 75% of cases and aminotransferase levels in 50%. Hyperbilirubinemia is uncommon and, when present, is indicative of biliary obstruction. The chest radiograph may reveal a right pleural effusion, basilar atelectasis, or elevated right hemidiaphragm. Ultrasound of the liver may reveal specific findings unique to amebic abscess, specifically a peripherally based, round or oval mass, with a well-circumscribed border and homogeneous hypoechoic center (Fig. 80.11). CT and magnetic resonance imaging (MRI) are alternative abdominal imaging modalities if ultrasonography is inconclusive. The diagnosis is supported by identification of a pathogenic protozoan in the stool. Even in cases of invasive intestinal disease, the yield may be low.

An enzyme-linked immunosorbent assay (ELISA) and counterimmune electrophoresis are the recommended diagnostic tests. The indirect hemagglutination test remains positive for an extended period and is therefore not helpful in establishing the presence of acute infection.

Management

Management of an amebic abscess consists of supportive therapy and initiation of amebicidal therapy. Metronidazole, 750 mg PO or IV tid for 7 to 10 days, is the therapeutic agent of choice. Most patients will respond to this regimen with percutaneous catheter drainage required only in refractory or complicated cases. The most serious complication of amebic liver disease is rupture into adjacent anatomic structures. Involvement of the lung occurs in 20% to 35% of cases of extrahepatic disease, often manifesting as a massive pleural effusion or consolidative pneumonia. With rupture into a bronchus, the patient can have cough productive of an anchovy paste–like substance or necrotic debris or frank hemoptysis. Abdominal pain with peritonitis can result from rupture into the abdominal cavity. Involvement of the pericardium occasionally is seen with lesions in the left lobe of the liver and can be catastrophic, either acutely as a consequence of pericardial tamponade or chronically from constrictive pericarditis.

Disposition

Select patients with amebic liver abscess can be managed as outpatients. This approach is best suited for those with mild clinical disease, stable living circumstances, and adequate access to medications and follow-up care. In patients with more severe disease, evidence of complications, or questionable social circumstances, hospitalization is advised.

**MISCELLANEOUS DISORDERS AND CONDITIONS OF THE LIVER**

Liver Disease in Pregnancy

The two primary hepatic disorders associated with pregnancy are benign cholestasis and acute fatty liver.
Benign Cholestasis

Benign cholestasis during pregnancy is common and has a familial linkage. Onset is in the third trimester and is heralded by the development of progressive pruritus. The bilirubin level may be elevated but not dramatically, so jaundice is uncommon. Laboratory tests reveal elevated alkaline phosphatase, 5′-nucleotidase, and bilirubin levels. Although the chief concern to the mother is discomfort from pruritus, the illness can be poorly for the fetus, with an increased incidence of prematurity, stillbirth, and fetal distress. Malabsorption of vitamin K can result in serious coagulopathy in the fetus, predisposing to spontaneous intracranial hemorrhage. Treatment is supportive and should include subcutaneous vitamin K for the mother antepartum and for the newborn after delivery. Cholestasis resolves without incident after delivery.

Acute Fatty Liver

Acute fatty liver of pregnancy is a malignant disorder that if unrecognized, can progress rapidly to maternal and fetal demise. The illness occurs in the latter part of the third trimester and is more common in primigravidas and twin pregnancies. The initial clinical features include fatigue, anorexia, nausea, and vomiting. Physical findings include mild jaundice and abdominal tenderness, most prominently in the midepigastrium and right upper quadrant. The liver may not be palpable because of the enlarged uterus.

Abnormal laboratory findings include moderate elevation of aminotransferase levels (5 to 10 times normal) hyperbilirubinemia, hypoglycemia, and evidence of disseminated intravascular coagulation—prolonged PT and partial thromboplastin time, hypofibrinogenemia, elevated fibrin split products, and thrombocytopenia. Treatment involves aggressive fluid and electrolyte support, glucose administration, and immediate delivery. Liver disease in pregnancy generally resolves without permanent sequelae after delivery.

Budd-Chiari Syndrome

Budd-Chiari syndrome is caused by hepatic venous outflow obstruction located anywhere above the level of hepatic venules. The disorder is associated with hypercoagulable states, such as factor V Leiden, protein S and C deficiency, thrombophilia, anti-thrombin III deficiency, myeloproliferative disorder, Behçet’s disease, paroxysmal nocturnal hemoglobinuria, and oral contraceptive use.

The clinical presentation varies from fulminant hepatic failure in acute high-grade obstruction to the insidious onset of jaundice to ascites in more subacute forms. Clinical symptoms correlate with the degree of venous obstruction and rate of venous occlusion. Fulminant disease is clinically indistinguishable from acute hepatic necrosis and hepatocellular disease secondary to viral infection. It is important to make the distinction between these two causes of hepatic failure early because treatment options differ. Prompt intervention in patients with Budd-Chiari syndrome offers the possibility of effective relief of signs and symptoms, with a potentially favorable outcome. Doppler ultrasound imaging of the hepatic vein has been reported to have a sensitivity of 85% to 95% for the diagnosis of Budd-Chiari syndrome and emerges as the diagnostic modality of choice in the ED setting.

The management of Budd-Chiari syndrome relates to the severity and acuity of disease. Newly diagnosed Budd-Chiari syndrome with acute decompensation will require immediate consultation and consideration for transjugular intrahepatic portosystemic shunt placement, percutaneous angioplasty, or thrombolytic therapy. Previously diagnosed disease with worsening ascites can be managed with modification of diuretics and therapeutic paracentesis, followed by referral to a primary care physician or gastroenterologist. Portacaval shunting and liver transplantation are options for disease refractory to medical or other less invasive percutaneous interventions.

Liver Transplantation

Human orthotopic liver transplantation offers a 5-year survival rate of approximately 80%, but complications are common. Early complications include bleeding, acute rejection, vascular and biliary tract problems, and infection. Delayed complications include malignancy, recurrence of underlying disease, infection, chronic rejection, medication toxicity, and renal failure. Many early complications will manifest during the immediate postoperative period. Delayed complications may occur 1 year or more after transplantation.

Liver transplant recipients are at increased risk for opportunistic infections as a consequence of their immunosuppressive therapy. Presenting signs and symptoms may be subtle. Chronic rejection manifests with low-grade temperature elevation, fatigue, and jaundice. Expected laboratory abnormalities include elevated bilirubin and transaminase levels, prolonged PT or INR, and low serum albumin level. Renal failure may not be clinically apparent until the glomerular filtration rate has declined significantly. Routine serum creatinine level measurement is the best means of identifying this disorder early, when successful intervention is still possible.

The most common combination of immunosuppressive agents used after liver transplantation includes a corticosteroid (eg, prednisone) along with a calcineurin inhibitor (eg, cyclosporine or tacrolimus) and sirolimus, mycophenolate, or azathioprine. Corticosteroid toxicity may produce glucose intolerance, osteoporosis, gastric ulceration, and muscle wasting. Cyclosporine and tacrolimus can cause renal impairment, which is the most common dose-limiting effect of these agents. Azathioprine can be hepatotoxic but is more often associated with bone marrow suppression, placing the patient at increased risk for infectious complications and bleeding diathesis.

Management of patients with complications related to their liver transplant is directed by the nature of the problem. Accordingly, assessment may include a complete blood count (CBC) and determination of glucose, BUN, creatinine, serum electrolyte, transaminase, bilirubin, and albumin levels, as well as coagulation studies. Hepatobiliary imaging is indicated if tumor, vascular occlusion, or biliary tract obstruction is suspected. Ultrasound studies with Doppler interrogation can be particularly useful in the ED setting. Consultation with a transplantation specialist is recommended for any patient with a problem potentially related to the organ transplant or immune-modulating medications.

BILIARY TRACT DISORDERS

CHOLELITHIASIS

Principles

The principal cause of biliary tract disease is related to the development of gallstones. There are two categories of gallstones, cholesterol stones and pigmented stones.

Cholesterol stones usually occur as a consequence of an elevated concentration of cholesterol in bile relative to the other principal constituents, bile acids and phospholipids. Bile acids and lecithin, the primary bile phospholipid, act in concert to solubilize cholesterol. As cholesterol levels rise or bile acid and lecithin levels decline, cholesterol has an increasing tendency to form crystals. These crystals, particularly in an incompletely
PART III  Medicine and Surgery  |  SECTION FIVE  Gastrointestinal System

emptying gallbladder, serve as a nidus for stone formation. Factors associated with an increased risk of cholesterol stone formation include increased age, female gender, massive obesity, rapid weight loss, cystic fibrosis, parity, drugs (eg, clofibrate, oral contraceptive agents), and familial tendency.

Pigmented stones are of two varieties, black and brown. Black stones occur exclusively in the gallbladder, contain a high concentration of calcium bilirubinate, and are usually encountered in older adults and those with intravascular hemolytic diseases (eg, sickle cell anemia, hereditary spherocytosis). Brown stones are associated with infection and can form in the gallbladder and intrahepatic and extrahepatic bile duct systems. Although bacterial infections are usually incriminated, parasites (eg, Ascaris lumbricoides, Clonorchis sinensis) have also been linked to brown stone formation. Both types of pigmented stones contain calcium bilirubinate and therefore may be visible on plain abdominal radiographs. For a stone to be radiopaque, it must contain at least 4% calcium by weight.

Clinical Features

The most common clinical manifestation of cholelithiasis is biliary colic. The pathophysiology is related to the passage of small stones from the gallbladder through the cystic duct into the common bile duct. The term colic is often misleading; affected patients commonly report steady pain, rather than intermittent or cramping discomfort. The pain most often is perceived in the RUQ but may be localized over a wide region of the upper abdomen. Radiation of pain, if it occurs, generally is to the base of the right scapula or shoulder. Associated signs and symptoms include nausea and vomiting, which may be severe enough to lead to fluid and electrolyte imbalances. Patients with biliary colic commonly report similar self-limited occurrences in the past and may offer an association between symptom onset and eating. Physical findings include mild tenderness to palpation, without guarding or rebound in the RUQ or epigastric region.

Differential Diagnosis

Considerations in the differential diagnosis of biliary colic include cholecystitis, peptic ulcer disease of the stomach or duodenum, pancreatitis, and hepatitis. Patients with cholelithiasis may occasionally have chest pain, so cardiopulmonary syndromes must be considered as well. A compatible clinical history in conjunction with normal laboratory test values (ALT, AST, lipase, and alkaline phosphatase levels), gallstones on ultrasound, and minimal or no tenderness in the RUQ favor the diagnosis of cholelithiasis. If abnormalities are not visualized, a chest radiograph or electrocardiogram may help differentiate between cardiopulmonary and biliary pathology.

Diagnostic Testing

No pathognomonic clinical laboratory findings are recognized; results of commonly performed tests typically are within normal limits. Important tests to perform include ALT and AST level measurements to evaluate for the presence of hepatitis, bilirubin and alkaline phosphatase level determinations to look for evidence of common duct obstruction, and lipase level measurement to assess for the presence of pancreatitis.

The diagnosis of biliary colic is made clinically in conjunction with the demonstration of stones in the gallbladder. Ultrasonography is the procedure of choice for investigating the gallbladder because it can be performed rapidly, is highly sensitive, and provides the added value of permitting the evaluation of surrounding structures (Fig. 80.12). Oral cholecystography with the use of iopanoic acid is an alternative (when ultrasonography is not available or cannot be performed successfully) and can identify gallstones in 95% of patients with cholelithiasis in whom the gallbladder can be visualized.

Management

The initial management of biliary colic is correction of fluid and electrolyte disturbances and relief of symptoms. Vomiting is managed with antiemetics and, if necessary, nasogastric suction. Pain often can be controlled with antispasmodics (eg, glycopyrrolate), nonsteroidal anti-inflammatory drugs (NSAIDs), and opiate analgesic agents, as needed. The definitive management of cholelithiasis usually involves surgical removal of the gallbladder; however, other options are available. Oral administration of bile acid (eg, chenodeoxycholate, ursodeoxycholate) over a period of months to years can result in dissolution of small to medium-sized stones. Extracorporeal shock wave lithotripsy may be successful in a select, technically suitable set of patients who have functioning gallbladders and, ideally, have a small number of stones.

The most common complication of biliary colic is fluid and electrolyte imbalances secondary to vomiting. Other adverse consequences include Mallory-Weiss tears from uncontrolled emesis and cholangitis from unrecognized and persistent common bile duct obstruction.

Special Considerations

Biliary colic is an uncommon symptom in children and is usually associated with an underlying hemolytic disorder (eg, sickle cell anemia, spherocytosis). Acute management of biliary colic is the same for children and adults.

Cholelithiasis may be encountered in pregnant women. Diagnosis in this population is made more difficult by the common occurrence of nausea and vomiting, particularly in the first trimester, and the presence of an enlarged uterus in later pregnancy, which alters anatomic relationships and interferes with an abdominal examination. Ultrasound imaging is of considerable diagnostic use in this setting. ED management is the same for pregnant and nonpregnant patients; however, definitive therapy generally is delayed until after parturition.

Disposition

Hospitalization should be considered for unremitting pain, intolerance of oral intake, significant electrolyte abnormalities, or
CHOLECYSTITIS

Principles

Acute cholecystitis is defined as sudden inflammation of the gallbladder. The risk factors for cholecystitis are similar to those for cholelithiasis—female gender, increasing age and parity, and obesity. Although gallstones play a prominent role in the pathogenesis of cholecystitis, a minority of cases are categorized as acalculous.

Obstruction of the cystic duct appears to be the critical factor in the development of gallbladder inflammation. Gallstones are identified in 95% of patients with cholecystitis and may be located in the common bile duct in many patients with acalculous cholecystitis. Causes of cystic duct obstruction unrelated to stone disease include tumor, lymphadenopathy, fibrosis, parasites, and kinking of the duct, which leads to filling and distention of the gallbladder. The ensuing inflammatory reaction may be related to mucosal ischemia from increased hydrostatic pressure or to the action of cytotoxic products of bile metabolism (eg, lysophosphatidylcholine). Although bacteria are isolated from the bile of inflamed gallbladders in most cases, the role of infection is not completely understood. Coliforms (eg, *E. coli*) represent the most common isolates, but anaerobes have been identified in as many as 40% of cases.

Clinical Features

The most common presenting symptom of cholecystitis is pain, usually in the right upper quadrant. Although the pain initially may be colicky, it will become constant in virtually all cases. A previous history of similar but less severe and self-limited symptoms is a valuable diagnostic clue, as is documentation of previous gallstones. Nausea and vomiting are typical features, and the patient may exhibit fever or describe radiation of pain, generally to the tip of the right scapula.

Physical findings include tenderness in the RUQ or epigastric region, often with guarding or rebound. Murphy’s sign (tenderness and an inspiratory pause elicited by palpation of the RUQ during a deep breath) is compatible with, but not specific for, gallbladder inflammation. Fever and tachycardia are commonly absent, so cholecystitis remains a diagnostic consideration in the absence of these findings in patients with abdominal pain and RUQ pain and tenderness to palpation.

Differential Diagnosis

Diagnostic considerations in addition to cholecystitis include hepatitis, hepatic abscess, pyelonephritis, right lower lobe pneumonia or pleurisy, pancreatitis, peptic ulcer disease of the duodenum with perforation or penetration, and appendicitis. Accurate diagnosis often requires the use of sonographic or, less commonly, scintigraphy or CT.

Diagnostic Testing

A polymorphonuclear leukocytosis with left shift is common, but a WBC count in the normal range has been seen in up to 40% of patients. Serum aminotransferase, bilirubin, and alkaline phosphatase levels may be mildly elevated but more often are within normal limits. An elevated lipase level should suggest the diagnosis of pancreatitis, instead of or in addition to cholecystitis. Plain abdominal radiographs may reveal calcified stones, gas in the gallbladder, or an upper quadrant sentinel loop, but are uncommon and nonspecific.

Ultrasound imaging is the most useful test in the ED. Visualization of the gallbladder without identification of stones has an extremely high negative predictive value for cholecystitis, whereas the presence of stones, thickened gallbladder wall, and pericholecystic fluid has a positive predictive value, in excess of 90% (Fig. 80.13).

Nuclear scintigraphy with technetium-99m–labeled iminodiacetic acid (IDA) generally is considered the most sensitive and specific imaging test for cholecystitis. IDA administered IV is taken up by hepatocytes and secreted into the bile canaliculi. Failure to obtain an outline of the gallbladder within 1 hour of administration of IDA in the presence of hepatic and common duct visualization proves cystic duct obstruction. In the appropriate clinical setting, this finding is diagnostic of cholecystitis. Conversely, visualization of the gallbladder and common duct within
PART III  Medicine and Surgery  |  SECTION FIVE  Gastrointestinal System

1 hour of administration has a high negative predictive value. Scintigraphy with IDA loses its sensitivity as the serum bilirubin level rises above 5 to 8 mg/dL; however, scintigraphy with diisopropyl IDA (diisopropyl iminodiacetic acid, or mebrofenin) allows visualization of the biliary tree in patients with total serum bilirubin in the range of 20 to 30 mg.

Although not the preferred imaging modality, CT can identify cholecystitis with a sensitivity of 92% and specificity of 99%. It is of particular value in cases of emphysematous and hemorrhagic cholecystitis.

Management

Supportive measures provide the foundation for initial management of acute cholecystitis—IV crystalloid administration to optimize volume status and antiemetics to manage emesis. Pain control can be addressed with NSAIDs or narcotic analgesics and possibly nasogastric suctioning, which may have the added benefit of diminishing the stimulus for biliary secretion and excretion, thereby adding to pain relief. Despite the questionable role of microbial infection in the pathogenesis of cholecystitis, antibiotics are recommended and should be continued until 1 day after the gallbladder is removed. Unless clinical evidence of sepsis exists, coverage with a single broad-spectrum antibiotic, such as IV piperacillin-tazobactam (3.375 g qid) is recommended.

The most serious complication of cholecystitis is gangrene of the gallbladder, with necrosis and perforation. Localized perforation may lead to pericholecystic abscess or fistula formation, with the latter predisposing to gallstone ileus at a later date. Patients with diabetes mellitus are at increased risk for bacterial infection may lead to pericholecystic abscess or fistula formation, with the latter predisposing to gallstone ileus at a later date. Patients with diabetes mellitus are at increased risk for bacterial invasion of the gallbladder wall and emphysematous cholecystitis (Fig. 80.14).

Special Considerations

Cholecystitis is uncommon in children; however, when it occurs, it should be managed as for adults. Cholecystitis in the pregnant woman poses challenges in diagnosis and therapy. Initial therapy is identical to that for the nonpregnant patient, but the issue of surgical intervention requires an individualized consultation between a surgeon and obstetrician.

Acalculous Cholecystitis. This is more common in older adults and most often is found in patients who are recovering from non–biliary tract surgery. Over the past decade, acalculous disease has been increasingly encountered as a complication of advanced acquired immunodeficiency syndrome (AIDS), usually secondary to infection with cytomegalovirus (CMV) or Crypto- sporidium. In comparison with calculous disease, acalculous cholecystitis tends to have a more acute and malignant course, with a high mortality rate. The same techniques are used to diagnose acalculous disease as for other forms of cholecystitis but are less sensitive and specific for this entity. Sonographic findings include thickening of the gallbladder wall, pericholecystic fluid, and lack of response to cholecystokinin. Scintigraphic findings are the same as for calculous disease.

Emphysematous Cholecystitis. This is an uncommon variant of cholecystitis, occurring in approximately 1% of cases. It is characterized by the presence of gas in the gallbladder wall, presumably consequent to the invasion of the mucosa by gas-producing organisms (eg, E. coli, Klebsiella spp., Clostridium perfringens). It is more common in diabetic patients, has a male predominance, and is acalculous in up to 50% of cases. Clinical presentation and physical findings are similar to those for cholecystitis. Plain radiographs or CT scans of the abdomen will reveal gas in the gallbladder wall. Because of a high incidence of gangrene and perforation, emergency cholecystectomy is recommended. Antibiotic coverage should include ceftriaxone, 1–2 g every 24 hours, plus metronidazole (500 mg IV tid) or monotherapy with a β-lactamase inhibitor or carbapenem. The mortality rate for emphysematous cholecystitis is approximately 15%.

Disposition

Hospitalization for antibiotic therapy and pain management is required. Surgery is recommended for patients with cholecystitis; however, the optimal timing for surgery is not certain. Surgery usually is performed after symptoms have subsided but while the patient is still hospitalized. Immediate cholecystectomy or cholecystotomy is reserved for the complicated case in which the patient has gangrene or perforation.

CHOLANGITIS

Principles

Acute obstructive cholangitis is usually the consequence of common duct blockage by a gallstone but may be associated with malignancy or a benign stricture. The key factors contributing to...
Cholangitis are obstruction, elevated intraluminal pressure, and bacterial infection. Incomplete obstruction occurs more commonly than complete blockage. Bacteria may gain access to the obstructed common duct in a retrograde manner from the duodenum, by way of the lymphatics, or from portal vein blood. The most commonly encountered organisms are similar to those encountered in other varieties of biliary tract disease—*E. coli, Klebsiella, Enterococcus*, and *Bacteroides*.

**Clinical Features**

Patients most often experience fever, chills, nausea, vomiting, and abdominal pain. The classic triad of physical findings first described by Charcot consists of RUQ pain, fever, and jaundice. These findings are compatible not only with cholangitis, but also with cholecystitis and hepatitis. Sepsis is a common complication and is evidenced by tachycardia, tachypnea, and frank hypotension. The presence of Charcot’s triad along with the clinical signs of sepsis—hypotension and altered sensorium—is referred to as Reynolds’ pentad.

**Differential Diagnosis**

Although patients with cholangitis generally have a higher fever and appear more ill than those with cholecystitis, considerable variability and overlap are possible. The presence of jaundice is the clinical sign most helpful in differentiating between these two disorders. An elevated bilirubin level is characteristic of cholangitis and uncommon in cholecystitis. Ultrasonographic evidence of dilated common and intrahepatic ducts usually is required to distinguish cholangitis from cholecystitis.

**Diagnostic Testing**

Common laboratory abnormalities include polymorphonuclear leukocytosis, hyperbilirubinemia, elevated alkaline phosphatase level, and moderately increased aminotransferase levels. Arterial blood gas measurements are useful to identify base deficit as an early sign of sepsis.

Sonography can be helpful if it demonstrates common and intrahepatic ductal dilation, whereas identification of stones in the gallbladder or common duct suggests the underlying cause of obstruction (see Fig. 80.12). Although nuclear scintigraphy cannot determine the cause, it is a more sensitive means to diagnose early obstruction. There is a high incidence of nonvisualization of the biliary tree with cholescintigraphy in patients with common duct obstruction when sonography fails to identify dilation.

Alternative imaging techniques include CT, percutaneous transhepatic cholangiography (THC), and endoscopic retrograde cholangiopancreatography (ERCP). Although these techniques may be more expensive and time-consuming, the latter two have the added benefit of offering potential therapeutic benefit. Endoscopic cholangioscopy can permit culture of bile, direct removal of obstructing stones, or decompression of the biliary tree by sphincterotomy or stent placement.

**Management**

Treatment of cholangitis includes hemodynamic stabilization with crystalloid fluid and, if necessary, vaspressors. Broad-spectrum antibiotic coverage should be initiated immediately after blood culture specimens have been obtained. The choice of antibiotics should be guided by local sensitivities and must provide coverage for enteric microbes. Table 80.4 lists antimicrobial therapies for cholangitis. The key to successful treatment is early biliary tract decompression, which may be achieved with THC, ERCP, or surgery.

**Disposition**

Patients with cholangitis require hospitalization, preferably in a monitored setting. Prompt consultation with a service that can provide for biliary tract decompression—surgery, interventional radiology, or gastroenterology—is necessary.

### SCLEROSING CHOLANGITIS

Sclerosing cholangitis is an idiopathic inflammatory disorder affecting the biliary tree characterized by diffuse fibrosis and narrowing of the intrahepatic and extrahepatic bile ducts. It is commonly associated with inflammatory bowel disease, particularly ulcerative colitis; however, in 25% of cases, it appears as an isolated disorder. Patients usually report weight loss, lethargy, jaundice, and pruritus. Rarely, infective cholangitis may develop. Prompt diagnosis may be challenging because of the sclerotic nature of the biliary tree and absence of duct dilation on ultrasound imaging. Surgical exploration or ERCP often is required for diagnosis. The management of uninfected cases is primarily symptomatic. Cholestyramine, a bile acid sequestrant, may diminish pruritus.

### AIDS CHOLANGIOPATHY

Manifestations of advanced HIV disease, generally associated with CD4+ counts less than 200/mm³, may include any one of a group of disorders collectively referred to as AIDS cholangiopathy. These disorders include bile duct strictures, papillary stenosis, and sclerosing cholangitis. The precise pathophysiology is not completely understood but is related to infection with CMV, *Cryptosporidium*, microsporidia, or *Mycobacterium avium* complex.

The clinical presentation is similar to that for other causes of cholangitis, with fever and RUQ pain. Laboratory test results include increased levels of alkaline phosphatase and minor elevations of transaminase levels. The bilirubin level is less commonly elevated than in other disorders that cause cholangitis. Ultrasonography generally is helpful in identifying bile duct stricture, thickening, or dilations, as are IDA scans. Management involves endoscopic sphincterotomy or stent placement in conjunction with treatment of the underlying infection.
KEY CONCEPTS

Hepatitis

Viral Hepatitis

The clinical presentation of viral hepatitis is highly variable, and many cases, particularly in children, are asymptomatic.

- Incubation times vary—Hepatitis A, 15–45 days; hepatitis B, 60–90 days; hepatitis C, 30–90 days.
- Highly effective immunizations exist against hepatitis A and B viruses.
- Postexposure, passive immunization exists for hepatitis A and B viruses but its use is mainly limited to nonimmunized, hepatitis B–exposed individuals.
- Direct-acting antiviral regimens using nucleoside inhibitors have revolutionized hepatitis treatment. A sustained virologic response with negative HCV RNA testing is achieved in over 90% of individuals.

Alcoholic Hepatitis

- Liver disease caused by alcohol use progresses from steatosis to cirrhosis, and finally to hepatocellular carcinoma. Hepatitis may accompany the cirrhosis.
- With cessation of alcohol intake, steatosis may reverse within 2 weeks.
- Alcoholic hepatitis, although generally a mild disease with minor clinical manifestations, can be a cause of fulminant hepatitis.
- Laboratory tests may help distinguish alcoholic hepatitis from viral hepatitis in that the former is associated with milder enzyme level elevations and a relative predominance of AST to ALT levels.
- Management of patients with alcoholic hepatitis should include fluid and electrolyte repletion, a high-calorie and vitamin-supplemented diet, and referral for alcohol dependence treatment.
- Variceal bleeding is treated with octreotide (50-µg bolus followed by 50 µg/h), somatostatin (250-µg bolus and 250-µg/hour infusion), or vasopressin (0.4-unit bolus followed by 0.4–1 unit/min continuous infusion) is important.
- Oral prednisone, 40 mg daily, or IV methylprednisolone, 32 mg daily, should be used for patients with alcoholic hepatitis and mDF more than 32.

Cirrhosis

Patients with cirrhosis most often present to the ED with complications of their disease—ascites, variceal bleeding, hepatorenal syndrome, or hepatic encephalopathy.

- Impaired hepatic synthetic and metabolic function in patients with cirrhosis may necessitate correction of coagulopathy before invasive procedures and modification of medication dosage.
- Prior to performing procedures, the targeted platelet count should be more than 50,000/mm³.
- When volumes more than 5 L are removed during paracentesis to treat ascites, albumin (8 g/L of ascitic fluid removed) should be given.
- Cryoprecipitate, 1 unit/10 kg body weight, is preferred over fresh-frozen plasma when treating liver-associated coagulopathies in a patient with active bleeding.
- Angiotensin-converting enzyme inhibiting drugs and angiotensin receptor blocking drugs should be avoided in patients with cirrhosis. Both lower mean arterial blood pressure and may increase mortality.
- Hepatorenal syndrome is heralded by an increasing creatinine level in the setting of liver failure. It is associated with a high rate of mortality and should be managed with norepinephrine, 0.5–3 mg/h in combination with albumin 1 g/kg (maximum, 100 g).

Hepatic Encephalopathy

- Hepatic encephalopathy is a state of cerebral and neuromuscular dysfunction secondary to increased ammonia levels and their effects on cerebral metabolism.

- The severity of hepatic encephalopathy does not directly correlate with the serum ammonia level.
- Consideration and evaluation for underlying exacerbating conditions, such as GI bleeding, hypokalemia, infection and dehydration, should be undertaken during the evaluation and treatment of hepatic encephalopathy.
- The differential diagnosis for hepatic encephalopathy should consider all causes of altered sensorium. The broad scope of the differential diagnosis may necessitate additional testing, including serum chemistry, CSF studies, toxicology studies, and head CT scanning.
- Management of hepatic encephalopathy includes correction of underlying electrolyte abnormalities, dietary guidance, administration of lactulose (30–60 g/day) and rifaximin (400 mg tid).
- L-Ornithine–L-arginine may be added to the regimen and has demonstrated ability to lower serum ammonia levels.
- Probiotics, acarbose, flumazenil, and polyethylene glycol require further investigation in the treatment of hepatic encephalopathy.

Spontaneous Bacterial Peritonitis

- SBP should be considered in any patient with ascites with abdominal pain, fever, or unexplained clinical deterioration.
- E coli and Klebsiella remain the two most commonly identified organisms in SBP.
- The diagnosis of SBP is dependent on obtaining ascitic fluid for cell count and culture.
- Use of leukocyte esterase reagent strips may provide a convenient means of bedside screening of ascitic fluid for SBP.
- An ascitic fluid granulocyte count greater than 250 cells/mm³ (100 cells/mm³ in peritoneal dialysis patients) is an indication for antibiotic treatment.
- Treatment of SBP includes cefotaxime, 2 g tid, for 5 days.
- Additional testing and imaging may assist in differentiating SBP from peritonitis secondary to other abdominal or lung pathologies.

Hepatic Abscesses

- Pyogenic abscesses often occur in the right lobe of the liver from anaerobic or aerobic microbes.
- Abdominal ultrasound and CT are the imaging modalities of choice.
- Imaging does not distinguish pyogenic from amebic abscesses.
- Treatment should be initiated prior to abscess drainage.
- Treatment regimens for pyogenic abscess include:
  - Cefotaxime + metronidazole
  - Ampicillin + gentamycin + metronidazole
  - Ciprofloxacin or levofloxacin or moxifloxacin + metronidazole
  - Piperacillin-tazobactam
  - Imipenem or meropenem, or doripenem or ertapenem
- Definitive treatment for abscesses larger than 3 cm includes image-guided percutaneous drainage.
- Surgical drainage is reserved for complex cases.

Amebic Abscess

- Although similar in many ways to pyogenic abscess, diagnosis is made via stool analysis or ELISA testing.
- Most patients will have elevation in alkaline phosphatase and aminotransferase levels.
- Ultrasound may reveal specific findings unique to an amebic abscess, including a peripherally located abscess with a well-circumscribed boarder and a homogeneous, hypoechoic center.
- Coupled with imaging, laboratory data including ELISA or counterimmune electrophoresis may aide in differentiating amebic from pyogenic abscesses.
- Definitive treatment of amebic abscess is amebicidal therapy with IV or oral metronidazole (750 mg tid for 7–10 days).

Cholelithiasis

- Biliary colic should be considered in patients with nausea, vomiting, and RUQ pain.
Diagnosis with ultrasound of the biliary system and possibly laboratory abnormalities suggests obstruction of the biliary tree. Initial management is supportive, with the goal of treating pain and correcting fluid and electrolyte abnormalities. Patients without findings of infection who are tolerating oral intake may be managed in the outpatient setting. Definitive care requires outpatient surgical referral for cholecystectomy.

**Cholecystitis**
- The vast majority of patients with cholecystitis have gallstones; however, approximately 8% have acalculous disease. The latter group of patients tend to have more severe disease and are at increased risk for complications.
- Despite an unclear relationship between bacterial infection and pathophysiology, antibiotic therapy is recommended.

**Cholangitis**
- Cholangitis is an emergency condition resulting from extrahepatic bile duct obstruction and bacterial infection.
- The classically seen triad consists of RUQ pain, fever, and jaundice.
- Effective management requires prompt fluid resuscitation and administration of broad-spectrum antibiotics.
- Definitive management includes hospitalization and early biliary tract decompression, which can be achieved surgically, transhepatically, or by ERCP.

80.1. Which of the following statements regarding hepatitis A is true?

A. Fecal shedding and highest infectivity coincide with symptomatic disease.

B. In the United States, approximately 20% of urban-dwelling adults are seropositive.

C. Occult disease is more common in children than in adults.

D. The incidence of it is fairly consistent across ethnic groups.

E. The most common risk factor for children is travel.

Answer: C. Children are more likely to have occult disease (up to 70%). Adult seropositive rates approach 50% among urban-dwelling adults. The incidence varies widely across ethnic groups. In areas of pediatric vaccinations, increasing adult cases are seen among intravenous drug users (IVDUs) and homosexual males. The stage of highest infectivity precedes symptoms.

80.2. Which of the following statements concerning hepatitis D infection is true?

A. Hepatitis D is spread primarily via the fecal-oral route.

B. Infection with hepatitis D is an independent event with a course nearly identical to that of hepatitis A.

C. It is common to see aspartate aminotransferase (AST) level elevations far in excess of alanine aminotransferase (ALT) level elevations.

D. Many cases are misdiagnosed as acute or reactivated hepatitis B.

E. Unconjugated bilirubin levels are 2 or 3 times higher than conjugated levels.

Answer: D. Hepatitis D virus infection can only occur with (co-infection) or after (superinfection) hepatitis B infection. It is spread via the parenteral route, such as by IV drug use. Many cases are misdiagnosed as acute or reactivation hepatitis B because B markers will be positive. There are no unique biochemical or laboratory patterns for any of the viral hepatitis infections. Hepatitis D does seem to have a direct cytotoxic potential as opposed to other viral causes, where the host immunologic response causes much of the hepatitis.

80.3. A 26-year-old man presents with complaints of pruritus and a raised rash for 7 days. The rash has been associated with nausea and painful symmetrical swelling of both wrists and metacarpophalangeal joints. He has no past medical history and takes no medications. He works in a retail store. Vital signs are normal, and the physical examination is remarkable for right upper quadrant tenderness, bilateral mild wrist effusion with minimal warmth and no erythema, and diffuse skin urticaria. The remainder of the examination is negative. Blood count, chemistry, and liver studies are remarkable for WBC, 11,800 cells/mm³, AST, 212 IU/L, ALT, 395 IU/L, normal alkaline phosphatase level, and total bilirubin of 2.3 mg/dL. Which of the following tests would be most likely to yield the diagnosis?

A. CMV titers

B. Hepatitis A antigen

C. Hepatitis B surface antigen

D. Herpes simplex 1 titers

E. Monospot test

Answer: C. A small number of patients with hepatitis B develop a prodrôme of arthralgias and arthritis (symmetric small joints) and dermatitis. The dermatitis is typically urticarial but may be macular, popular, or petechial.

80.4. Scleral icterus becomes clinically apparent at approximately which serum bilirubin level?

A. 2 mg/dL

B. 2.5 mg/dL
The WBC count may range from low, with lymphocytic predominance, to a polymorphonuclear (PMN)-predominant leukocytosis. ALT is almost always elevated in excess of AST. Lactate dehydrogenase (LDH) levels are almost always normal.

The alkaline phosphatase level is rarely elevated more than 2 or 3 times normal, and LDH levels are modestly elevated. The WBC count may range from low, with lymphocytic predominance, to a polymorphonuclear (PMN)-predominant leukocytosis. ALT is almost always elevated in excess of AST.

A 26-year-old woman returns for follow-up after initial evaluation for possible acute hepatitis. Her hepatitis panel has returned with the following results:

<table>

Which of the following diagnosis is the most appropriate?
A. Acute hepatitis A
B. Acute hepatitis B
C. Immunity to hepatitis B
D. Previous hepatitis A
E. Previous hepatitis B

Acute hepatitis A is characterized by IgM to hepatitis A. Prior infection is determined by IgG antibody. Acute hepatitis B is characterized by the presence of surface antigen and IgM antibody to core antigen. Surface antigen alone may be absent late in the course of the disease or may present chronically unrelated to the current episode. IgG to the core antigen indicates previous infection. IgG to the surface antigen is the best marker for immunity.

A 39-year-old man presents with a 4-day history of abdominal pain and nausea. He has no significant past history and takes no medications. Vital signs are temperature, 37.7°C (99.9°F) oral, heart rate (HR), 98 beats/min, respiratory rate (RR), 20 breaths/min, and blood pressure, 119/68 mm Hg. The physical examination reveals scleral icterus, a normal cardiopulmonary examination, moderate right upper quadrant tenderness without rebound, and guaiac-negative stool. Laboratory assessment reveals the following:

Answer: B. Icterus is often first noted in the sublingual or subungual areas.

Answer: B. The alkaline phosphatase level is rarely elevated more than 2 or 3 times normal, and LDH levels are modestly elevated. The WBC count may range from low, with lymphocytic predominance, to a polymorphonuclear (PMN)-predominant leukocytosis. ALT is almost always elevated in excess of AST.

Answer: B. The alkaline phosphatase level is rarely elevated more than 2 or 3 times normal, and LDH levels are modestly elevated. The WBC count may range from low, with lymphocytic predominance, to a polymorphonuclear (PMN)-predominant leukocytosis. ALT is almost always elevated in excess of AST.

Answer: A. Admission for observation and GI consultation
B. CT scan of the abdomen with contrast
C. Gastrointestinal (GI) referral for interferon therapy
D. Reassurance
E. Tapering course of corticosteroids

Answer: E. This is equivalent to a six-pack of beer, four to six glasses of wine, or three or four mixed drinks daily. For women, the risk increases with a daily consumption of more than 20 g of alcohol.

Answer: A. Prior infection is determined by IgG antibody. Acute hepatitis B is characterized by the presence of surface antigen and IgM antibody to core antigen. Surface antigen alone may be absent late in the course of the disease or may present chronically unrelated to the current episode. IgG to the core antigen indicates previous infection. IgG to the surface antigen is the best marker for immunity.

Answer: A. Admission for observation and GI consultation
B. CT scan of the abdomen with contrast
C. Gastrointestinal (GI) referral for interferon therapy
D. Reassurance
E. Tapering course of corticosteroids

Answer: A. Altered sensorium and prolongation of the PT beyond 5 seconds or INR beyond 1.5 suggest fulminant hepatic failure. Similarly, an unexplained elevation of the BUN or creatinine level may portend hepatorenal syndrome, which can be fatal. The BUN level elevation in this hepatitis patient warrants admission for hydration, close observation, and GI consultation. Interferon has had some success in symptomatic hepatitis B patients but does not affect the early course. There is no role for corticosteroids.

Answer: E. This is equivalent to a six-pack of beer, four to six glasses of wine, or three or four mixed drinks daily. For women, the risk increases with a daily consumption of more than 20 g of alcohol.
Answer: A. Ammonia accumulates in severe liver disease and crosses the blood-brain barrier to eventually form glutamine. Ammonia levels correlate poorly with encephalopathy. Lactulose is an osmotic cathartic that acidifies colonic contents, causing ammonia trapping. Neomycin is a poorly absorbed aminoglycoside that reduces colonic bacteria but is relatively contraindicated in cases of renal insufficiency. Therapies for hepatic encephalopathy that have been under clinical investigation include metronidazole, zinc, flumazenil, and eradication of Helicobacter pylori. Vitamin K would have modest benefit due to loss of hepatic synthetic abilities. Plasma would not be indicated unless active bleeding occurred.

80.10. A 23-year-old G2P1 woman at 35 weeks of gestation presents with 3 days of fatigue, anorexia, nausea, and vomiting. She reports moderate epigastric and right upper quadrant pain. The physical examination is remarkable for icteric sclerae, slightly dry mucous membranes, and moderate tenderness in the right upper quadrant. She is afebrile and her uterus is not tender. Urgent ultrasound shows a viable moving fetus at 34 weeks’ estimated gestational size, with good cardiac activity, and liver and gallbladder ultrasound reveals no obvious gallstones or ductal dilatations but moderate hepatomegaly. Laboratory analysis is remarkable for the following:

Answer: E. Acute failing liver of pregnancy typically presents in the latter third trimester. Treatment involves aggressive fluid and electrolyte support, glucose administration, and immediate delivery. Liver disease generally resolves without sequelae. The illness is more common in primigravidas and twin pregnancies.

80.11. What is the most sensitive and specific imaging test for acute cholecystitis?

Answer: B. IDA administered IV is taken up by hepatocytes and secreted into bile canaliculi. Visualization of the gallbladder and common duct within 1 hour has a negative predictive value of 98%. Scintigraphy with IDA loses its sensitivity at bilirubin levels of 5 to 8 mg/dL.
CHAPTER 81

Pancreas

Rachel Berkowitz | Gabriel Rose

**ACUTE PANCREATITIS**

**Background**

Acute pancreatitis is an inflammatory condition that occurs when enzymatic autodigestion and an inflammatory cascade result in destruction of pancreatic tissue. Its presentation may range widely from mild, self-limited disease to sepsis and multiorgan failure. Recurrent intermittent bouts of acute pancreatitis may result in morphologic and functional changes of the gland, known as chronic pancreatitis.

The overall mortality due to acute pancreatitis is 4% to 10%, although in severe cases mortality may be as high as 30%. Although mortality from acute pancreatitis has decreased with improvements in recognition, understanding, and therapy, the annual incidence of the disease and number of hospital admissions attributed to it have been trending upward.

**Causes**

There are numerous causes of acute pancreatitis (Box 81.1); however, the most common causes in the United States are gallstones (40%–70%) and chronic alcohol consumption (25%–35%). In women, the diagnosis is usually related to gallstones, whereas in men it is usually alcohol-related. Endoscopic retrograde cholangiopancreatography (ERCP) is the third leading cause of acute pancreatitis, followed by drugs and trauma. Less common causes include infection, hypertriglyceridemia (serum triglyceride levels > 1000 mg/dL), hypercalcemia, tumors, genetic enzymatic defects, and gland architectural anomalies. In 10% to 30% of cases, the cause remains unknown, although it is thought that many of these idiopathic cases are due to occult microlithiasis. The risk of biliary pancreatitis is actually correlated with the decreasing size of gallstones. Smoking and diabetes are independent risk factors for the development of pancreatitis.

**Anatomy and Physiology**

The pancreas is a retroperitoneal organ with endocrine and exocrine functions (Fig. 81.1). It contains three segments—head, body, and tail—that span across the upper abdomen. The pancreatic head sits within the concave C loop of the duodenum, located in the epigastrium. The body of the pancreas traverses posteriorly to the stomach, and the pancreatic tail abuts the hilum of the spleen in the left upper quadrant. A large main pancreatic duct (duct of Wirsung) courses within the pancreas from the tail to the head, where it meets the common bile duct to form the ampulla of Vater, which drains its contents into the duodenum via the sphincter of Oddi.

The exocrine function of the pancreas is carried out by the excretion of various digestive enzymes, such as trypsinogen. The endocrine function of the pancreas includes secretion of the regulatory hormones insulin, glucagon, and somatostatin.

**Pathophysiology**

Acute pancreatitis begins with an initial inciting event, such as exposure to a toxin or pharmacologic agent, or duct obstruction by gallstones. Cellular injury disrupts normal membrane trafficking and triggers the inappropriate activation of trypsinogen and other digestive enzymes. This in turn leads to autodigestion of pancreatic tissue and stimulation of an inflammatory cascade, which further damages the pancreas. Locally, cytokines cause increased vascular permeability, which can result in complications such as edema, hemorrhage, and/or necrosis. Systemically, inflammatory mediators may lead to a systemic inflammatory response syndrome (SIRS) response and potentially sepsis and shock. Bacteremia may occur due to translocation of intestinal flora. Distant organ dysfunction manifested, for example, by pleural effusions, acute respiratory distress syndrome, and renal failure, may also ensue.

**Disease Classification**

Acute pancreatitis can be classified by type—interstitial edematous versus necrotizing pancreatitis—and by local complications. Most patients have the interstitial edematous type, which usually resolves within the first week of illness. About 5% to 10% of patients develop necrotizing pancreatitis, which can involve the pancreatic parenchyma and surrounding tissue. Local complications involving the pancreas, as defined by the revised 2012 Atlanta Classification, are categorized based on whether they occur in the setting of interstitial or necrotizing pancreatitis and whether they are encapsulated (Box 81.2).

**Clinical Features**

Patients with acute pancreatitis typically complain of the rapid onset of constant epigastric or left upper quadrant pain. Pain is usually of moderate to severe intensity, with intensity having no correlation with disease severity. The pain may radiate to the mid back or flanks, sometimes in a bandlike distribution, and may be accompanied by nausea and vomiting. Patients often relate previous episodes of similar pain, relating to biliary colic or mild bouts of pancreatitis.

The general appearance is often notable for a patient who is restless and in moderate distress, searching for a position of comfort, such as bending forward. Vital signs commonly reflect patient discomfort or an existing inflammatory process, with rises in temperature, heart rate, or respiratory rate. Blood pressure may be slightly elevated secondary to pain, although in severe or complicated cases hypotension and signs of shock may be present.
Jaundice can be caused by an obstructing gallstone. Respirations may be shallow due to splinting from pain. Pulmonary examination may reveal decreased breath sounds or basilar crackles in the setting of pulmonary complications.

The abdomen can appear normal or distended. Classic descriptions of Cullen’s sign (bluish periumbilical discoloration due to hemoperitoneum) and Grey Turner’s sign (reddish-brown discoloration around the flanks due to retroperitoneal bleeding) are rarely seen but, in cases of hemorrhagic necrotizing pancreatitis, can carry a poor prognosis. Auscultation of the abdomen may reveal normal, diminished, or absent bowel sounds if the patient has concomitant ileus. Palpation of the abdomen often reveals epigastric tenderness with guarding, with rebound tenderness being a less common finding. Right upper quadrant tenderness and the presence of Murphy’s sign may be seen in cases of gallstone pancreatitis.

**Box 81.1**

**Causes of Acute Pancreatitis**

**TOXIC—METABOLIC**
- Alcohol
- Drugs
- Hyperlipidemia
- Hypercalcemia
- Uremia
- Scorpion venom

**MECHANICAL—OBSTRUCTIVE**
- Biliary stones
- Congenital—pancreas divisum, annular pancreas
- Tumors—ampullary, neuroendocrine, pancreatic carcinoma
- Post-ERCP
- Ampullary dysfunction or stenosis
- Duodenal diverticulum
- Trauma

**INFECTIONOUS**
- Viral—mumps, coxsackie, HIV, CMV, EBV, varicella
- Bacterial—TB, *Salmonella*, *Campylobacter*, *Legionella*, *Mycoplasma*
- Parasitic—*Ascaris*

**VASCULAR**
- Vasculitis
- Embolism
- Hypoperfusion, ischemia
- Hypercoagulability

**OTHER**
- Idiopathic
- Hereditary
- Diabetes mellitus, DKA
- Autoimmune

CMV, Cytomegalovirus; DKA, diabetic ketoacidosis; EBV, Epstein-Barr virus; ERCP, endoscopic retrograde pancreatography; HIV, human immunodeficiency virus; TB, tuberculosis.

**Box 81.2**

**Local Complications of Acute Pancreatitis**

**INTERSTITIAL EDEMATOUS PANCREATITIS**
- Acute peripancreatic fluid collection—homogeneous fluid collection adjacent to pancreas; seen within 4 wk of symptom onset
- Pancreatic pseudocyst—homogeneous fluid collection with well-defined wall; seen >4 wk from symptom onset

**NECROTIZING PANCREATITIS**
- Acute necrotic collection—heterogeneous collection of fluid and necrosis; intrapancreatic and/or extrapancreatic
- Walled-off necrosis—heterogeneous collection of fluid and necrosis with well-defined wall; intrapancreatic and/or extrapancreatic; seen >4 wk from symptom onset

In addition to the direct injury to the pancreas, patients may have local complications involving surrounding structures—for example, bowel necrosis, splenic or portal vein thrombosis, gastrointestinal bleeding, or gastric outlet obstruction. Most of these tend to be late findings.

Systemic complications are related to the progression of local inflammation and may result in SIRS. Although in most cases these conditions resolve within days, if persistent there may be progression to fulminant sepsis, shock, and organ failure, especially if there is underlying chronic disease. The pulmonary, cardiovascular, and renal systems are the most important determinants when assessing for organ failure. Increased microvascular permeability is the primary cause of pulmonary sequelae, although enzymatic degradation of surfactant may also play a role. Patients may develop acute respiratory distress syndrome, atelectasis, or pleural effusion, manifested as hypoxemia or respiratory distress. Pleural effusions are present in up to 50% of patients and tend to develop more frequently on the left side. Cardiovascular collapse, as evidenced by decreased mean arterial pressure or the need for inotropic support, may develop as shock results from fluid shifts and volume loss. Renal failure, demonstrated by an elevated creatinine level, may arise from a combination of hypoperfusion and the effects of inflammatory mediators.

In addition, coagulopathy occurs from cytokine-mediated activation of the coagulation cascade, potentially leading to thrombocytopenia or disseminated intravascular coagulation. Metabolic abnormalities are also common. Hyperglycemia results from decreased insulin production and hypocalcemia from low albumin and magnesium levels.

### Differential Diagnoses

A number of disease processes have the ability to mimic the presentation of acute pancreatitis and should be considered in the differential diagnosis (Box 81.3). Inflammation of nearby intra-abdominal organs, such as the gallbladder, stomach, and duodenum, are often characterized by a similar pattern of epigastric or upper quadrant abdominal pain. Myocardial infarction, pneumonia, and aortic pathology may also present as lower thoracic or upper abdominal pain, with radiation to the back.

</tr>
</thead>
<tbody>
<tr>
<td>Sickle cell crisis</td>
<td>Confirmation of pancreatitis with abdominal imaging is done by computed tomography (CT) or, less commonly, magnetic resonance imaging (MRI) or ultrasound. Although CT is very sensitive and specific for acute pancreatitis, it is not routinely needed for the diagnosis or indicated in the emergency department (ED). CT is only recommended in the following circumstances: (1) in cases of diagnostic uncertainty—for example atypical abdominal pain—or normal pancreatic enzyme levels in the setting of high clinical suspicion; (2) to rule out other suspected intra-abdominal pathology—for example, bowel obstruction or aortic aneurysm; and (3) to assess for complications in patients who fail to respond to appropriate therapy after at least 48 hours. The evaluation of complications by CT is best done at least 3 to 7 days after presentation. During the first few days, CT does not accurately identify the degree of pancreatic necrosis, typically underestimating its extent. Complications such as abscess and pseudocyst do not generally develop until several weeks after the onset of symptoms. Studies of patients undergoing early CT have found no benefit compared to delayed imaging.</td>
</tr>
<tr>
<td>Diabetic ketoacidosis</td>
<td></td>
</tr>
</tbody>
</table>
If CT is performed, it should be done with intravenous (IV) contrast. The CT scan is normal in 15% to 30% of patients with mild cases of pancreatitis. Abnormal findings include enlargement of the gland and loss of its typical texture and borders. As disease worsens, CT shows decreased or heterogeneous enhancement and increased inflammatory signs, such as surrounding fluid and fat stranding (Fig. 81.2). Pancreatic necrosis is suggested by areas demonstrating no enhancement (Fig. 81.3). In cases for which contrast is contraindicated, CT without contrast may still be useful; alternatively, MRI can be performed.

MRI findings of pancreatitis are similar to those of CT. MRI provides superior imaging of the gallbladder and biliary tract, but is more costly and has limited availability. Ultrasound may show an edematous swollen pancreas, but the study image is often obscured by bowel gas. Although it has limited value in the diagnosis of pancreatitis, ultrasound is sensitive for imaging biliary disease and should be performed early following the diagnosis of pancreatitis to help determine the cause. Abdominal radiographs show primarily nonspecific findings and do not contribute to the diagnosis of pancreatitis. Chest radiography should be performed when pulmonary complications are suspected.

Predicting Disease Severity

Although the diagnosis of pancreatitis is relatively straightforward, predicting the disease course is difficult. A number of classification schemes and severity scoring systems have been developed, but none are particularly helpful in the ED at the time of initial patient presentation.

The 2012 Atlanta Classification, developed by international consensus to provide a universally applicable system for categorizing pancreatitis severity, is widely recognized (Box 81.4). Based on

**BOX 81.4**

**Revised Atlanta Classification of Acute Pancreatitis**

**MILD**

No organ failure
No local or systemic complications

**MODERATE**

Transient organ failure (<48 h)
Local or systemic complications

**SEVERE**

Persistent organ failure (>48 h)

---

*Organ failure defined as a modified Marshall score of 2 or more for the respiratory, cardiovascular, or renal system.

this classification, a patient cannot be diagnosed with severe pancreatitis until 48 hours following presentation, further underlining the dynamic nature of pancreatitis and difficulty in predicting severity at the time of ED evaluation. Scoring systems for assessing the severity of pancreatitis are based on using combinations of a variety of clinical features, vital signs, and serum markers. One of the oldest and most well-known is Ranson’s criteria (Box 81.5). This system uses five criteria evaluated at presentation and six criteria evaluated 48 hours later. The total number of criteria present determine a score that can be used to predict the associated mortality rate. Another commonly used scoring system is the Acute Physiology and Chronic Health Evaluation II (APACHE II), which was designed as an intensive care unit (ICU) instrument and consists of 15 variables. A Ranson’s score more than 3 or APACHE II score more than 8 is considered high risk for severe disease. There is also a classification system based on imaging for patients who undergo CT. The modified CT severity index (CTSI) allots points for various CT findings, such as pancreatic inflammation, pancreatic necrosis, fluid collections, and extrapancreatic complications. The score has been shown to correlate with hospital length of stay and development of organ failure, but is no more accurate than clinical scoring systems in predicting outcomes (Table 81.1).11

These systems have been criticized for their complexity, inadequate sensitivity or specificity, reliance on data that may not be immediately available, and inability to calculate a score at presentation. As a result, newer and less cumbersome schemas have been proposed. The bedside index for severity in acute pancreatitis, BISAP, is a newer scoring system based on five factors: blood urea nitrogen level, impaired mental status, SIRS, age, and pleural effusions.12 Compared to other scoring systems, it has lower sensitivity and similar specificity.13 According to the Harmless Acute Pancreatitis Score (HAPS), in patients with no peritonitis (no rebound or guarding) and normal hematocrit and creatinine levels, there is a very low risk of mortality, necrosis, or need for hemodialysis or ventilatory support. HAPS has been shown to be 97% specific for mild disease, although not sensitive.14 Several isolated serum markers have also been proposed as indicators of severity. C-reactive protein is the most helpful due to its high sensitivity and wide availability; however, its level does not peak until 72 hours following the onset of symptoms. Interleukin-6 and procalcitonin have also shown promise as single markers.

Management

The treatment of acute pancreatitis is mainly supportive. Volume replacement is important because patients with pancreatitis are often volume-depleted from decreased oral intake, emesis, diaphoresis, or third-spacing of fluids. Early fluid resuscitation reduces the incidence of SIRS and organ failure at 72 hours.15 IV fluid resuscitation within the first 24 hours appears to be more important than the total volume received at 48 hours.16 Fluid resuscitation should be targeted toward reversing hypotension and hemoconcentration and preserving urine output. Hematocrit, blood urea nitrogen, and creatinine can be used as surrogate markers for these goals. Both normal saline (NS) and lactated Ringer’s (LR) solutions are good fluid choices. If available, we prefer LR because it appears to result in better outcomes.17 In large volumes, NS use can lead to the development of a hyperchloremic metabolic acidosis. Acidosis is known to be detrimental in shock states, contributing to the systemic inflammatory cascade. Furthermore, a low pH activates trypsinogen, which makes the pancreatic acinar cells more prone to injury, thereby worsening the severity of pancreatitis.

As fluid status is being corrected, electrolyte levels may also need to be addressed. Hypocalcemia is frequently due to hyperalimentation, so calcium replacement is not necessary unless the ionized calcium level is low or the neuromuscular effects of hypocalcemia, such as Chvostek’s or Trousseau’s signs, are present. If there is concurrent hypomagnesemia, repletion with magnesium may correct the hypocalcemia. Hyperglycemia results from impaired insulin release, increased gluconeogenesis, and alterations in glucose uptake. Some patients will require exogenous

insulin because untreated hyperglycemia may contribute to worsening pancreatitis and immune function.

Pain control is another important aspect of management. Opioids are often required because the pain associated with pancreatitis is typically severe. When available, we prefer to use patient-controlled analgesia. Although there is a theoretical risk of morphine causing spasm of Oddi sphincter, there are no clinical studies showing that the administration of morphine causes or worsens pancreatitis or cholecystitis. There are also very little data comparing the efficacy of different opioids for the relief of pain in pancreatitis. Antiemetics may also be needed for symptomatic relief.

It was once thought that oral or enteral nutrition would worsen pancreatitis by stimulating the secretions of the exocrine pancreas and thereby autodigestion; however, we now know that this does not occur and withholding enteral feeding actually has detrimental effects. It leads to increased gastrointestinal mucosal atrophy and permeability and amplifies bacterial overgrowth and translocation of gut bacteria. It has also been established that total parenteral nutrition is associated with many complications. Therefore, oral or enteral nutrition is the preferred method of feeding and may actually be therapeutic. In moderate to severe cases of pancreatitis, early enteral feeding by nasogastric or nasojejunal tube is safe and effective. In mild cases, early oral feeding is safe and may lead to less days of hospitalization. A low-fat, solid diet is as safe as clear liquids and can be given as tolerated.

Antibiotics are not indicated for the prevention of infectious sequelae. Even in severe cases of pancreatitis, antibiotic prophylaxis has not been shown to improve mortality or the need for surgical intervention. Their use should be limited to infected necrotizing pancreatitis or extrapancreatic infections such as cholangitis and bacteremia. SIRS features such as tachycardia and tachypnea are common in acute pancreatitis but are nonspecific and do not necessarily portend sepsis or organ failure. However, during the initial ED presentation, it may be difficult to rule out sepsis as the cause. Therefore antibiotics should be initiated if there is suspicion of an infectious source, but not based on SIRS criteria alone. In cases of known infected pancreatic necrosis, the chosen antibiotic regimen should cover gram-negative and gram-positive bacteria as well as anaerobes. A quinolone plus metronidazole (ciprofloxacin, 400 mg, and metronidazole, 500 mg bid) or a carbapenem (meropenem, 1 g, or imipenem-cilastatin, 500 mg to 1 g tid) are suitable regimens due to bacterial coverage and pancreatic tissue penetration.

Protease inhibitors and histamine 2 (H2) blockers have been proposed as treatment options for acute pancreatitis in the past, but are no longer recommended because studies have shown no effect on clinical outcomes.

Early ERCP is indicated for patients with cholangitis or biliary obstruction and is recommended within 24 hours of admission. Studies have shown no benefit for other patients with pancreatitis, regardless of predicted severity. Because of the potential complications associated with ERCP, it should not be performed unless there is evidence of cholangitis or biliary obstruction, such as jaundice, elevated bilirubin level, and signs of sepsis. Suspicion of cholangolithiasis based on a dilated biliary tree on CT does not itself warrant ERCP. Magnetic resonance cholangiopancreatography (MRCP) or endoscopic ultrasound (EUS) is recommended for further evaluation in this case.

Surgical intervention is rarely indicated at the time of presentation. It is recommended that patients with mild biliary pancreatitis undergo cholecystectomy during the index admission, but not emergently. Asymptomatic pancreatic necrosis and pseudocysts do not need treatment. Infected or symptomatic necrotizing pancreatitis often requires surgical, endoscopic, or radiologic intervention, but not until approximately 4 weeks later, when the collection becomes walled off.

**Disposition**

It is possible to discharge patients with mild presentations whose symptoms are adequately controlled, are tolerating oral intake, and have no signs of complications. However, due to the unpredictable course of pancreatitis, hospital admission for further observation and management is typically warranted. Most patients with acute pancreatitis have mild cases. They are easily managed on a general medical floor and usually discharged within 1 week. About 20% will suffer complications and require a longer hospital stay or higher level of care.

The following features should prompt consideration of ICU admission—moderately severe pancreatitis (according to the revised Atlanta classification), continued need for volume resuscitation, persistent SIRS, significant electrolyte abnormalities, older age, or other factors that render a patient high risk for deterioration. Patients who may need endoscopic, surgical, or interventional radiology procedures should be managed in or referred to a specialist center, defined as a high-volume center with daily access to these services. A nationwide analysis has shown that admission to a hospital with an annual volume of acute pancreatitis cases in the highest third is associated with shorter lengths of stay and lower mortality.

**CHRONIC PANCREATITIS**

Chronic pancreatitis is a progressive inflammatory disorder of the pancreas in which the parenchyma of the gland is gradually replaced by fibrous tissue. It is most commonly diagnosed in middle age, with a mean age at diagnosis of 62 years. The risk is at least twice as high for men compared to women and for African Americans compared to whites.

Pancreatitis exists as a spectrum, with acute pancreatitis leading to recurrent acute pancreatitis, which in turn leads to chronic pancreatitis. Only a minority of patients progress across this spectrum, with evolution dependent on a number of environmental and hereditary factors. Chronic pancreatitis can be classified as toxic-metabolic, obstructive, genetic, autoimmune, related to recurrent and postnecrotic acute pancreatitis, or idiopathic. Alcohol abuse is the most common cause. Increased risk is associated with alcohol consumption more than five drinks/day. Smoking is also a well-established independent risk factor. The exact mechanisms whereby the various risk factors ultimately result in disease are not entirely understood; however, there is a common pathophysiologic pathway involving progressive inflammation and fibrosis, leading to acinar cell dysfunction and morphologic changes that impair endocrine and exocrine functions. Patients may subsequently develop malnutrition and diabetes and, in some cases, pancreatic cancer.

**Clinical Features**

Patients with chronic pancreatitis may present with prolonged or recurrent abdominal pain, findings relating to local complications and structural changes (eg, bowel obstruction, vascular thrombosis), or signs of pancreatic endocrine and exocrine dysfunction (eg, glucose intolerance, malabsorption, steatorrhea). The nature of the abdominal pain will often be similar to that of acute pancreatitis, described as severe, constant epigastric pain radiating to the mid back, often associated with nausea and vomiting. Food and alcohol intake tend to exacerbate the pain, and weight loss is common. It has been proposed that as the disease process continues, pain may diminish due to progressive loss of functional acinar cells, but evidence has been conflicting.

On physical examination, patients may appear jaundiced due to alcoholic cirrhosis or biliary obstruction or ill from prolonged malnutrition and malabsorption. The abdomen is usually tender,
and a palpable mass representing a pancreatic pseudocyst or tumor may be appreciated.

Differential Diagnoses

The diagnosis of chronic pancreatitis may be relatively clear-cut in a patient with a history of recurrent pancreatitis or frequent pain that is typical in the presence of risk factors for pancreatitis. However, other diagnoses should always be considered because these patients may also have pathology unrelated to the pancreas or complications of pancreatitis. The list of alternative diagnoses is similar to that for acute pancreatitis (see Box 81.3); however, chronic, chronic abdominal processes, such as peptic ulcer disease, gastritis, biliary colic, and irritable bowel syndrome are more consistent with recurrent episodes of upper abdominal pain. In addition, patients with chronic pancreatitis who are opioid-dependent may have withdrawal symptoms that mimic an exacerbation of pancreatitis.

Diagnostic Testing

The initial diagnosis of chronic pancreatitis is made by one of several imaging modalities, including CT, MRCP, or EUS. CT findings include dilated pancreatic ducts, atrophy, microcalcifications, and complications such as pseudocyst. MRCP and EUS are accurate methods for visualizing pancreatic parenchymal and ductal changes. EUS is the most sensitive imaging test for chronic pancreatitis and is best able to detect subtle and early changes. ERCP has mostly been replaced by MRCP because ERCP is invasive and carries a 4% risk of precipitating pancreatitis. These imaging techniques can also rule out pancreatic cancer, which is important because 5% of patients with pancreatic cancer are initially misdiagnosed with chronic pancreatitis.

For acute exacerbations of chronic pancreatitis, the same diagnostic principles apply as for acute pancreatitis—clinical features, laboratory analysis, and imaging. However, laboratory tests are less helpful in chronic pancreatitis because serum lipase and amylase levels do not rise to the same degree and may be normal. Liver function test results (eg, transaminase, alkaline phosphatase, bilirubin levels) may be elevated in patients with concurrent alcoholic liver disease or biliary duct obstruction. Hypocalemia and hypoalbuminemia are common, and impaired pancreatic endocrine function may be reflected by hyperglycemia. Although an abdominal radiograph is not necessary, up to 30% of patients have a characteristic finding of pancreatic calcification, which is pathognomonic for the disease.

Management

The treatment of chronic pancreatitis is supportive and largely focused on pain relief and correction of fluid and electrolyte imbalances. Acetaminophen and nonsteroidal antiinflammatory drugs (NSAIDs) are the preferred initial agents, although escalation to tramadol or a more potent opioid analgesic is often necessary. In patients who fail traditional medical management, other pain control options with varying supportive evidence include oral enzyme replacement, octreotide, antioxidants, and celiac plexus block. Referral to a pain management specialist may be beneficial because pain can be difficult to control and the risk of addiction is significant.

Beyond ED care, endoscopy may be indicated for the drainage of symptomatic pseudocysts and ductal leaks that result in ascites or for stenting obstructed bile ducts. Surgery is aimed at the restoration of gastrointestinal function and pain relief by decompression of ductal obstruction, which is usually reserved for patients for whom conservative medical treatments have failed. Nutrition replacement, along with lifestyle modifications such as avoidance of alcohol and cigarettes, are also important in the long-term treatment of chronic pancreatitis.

Disposition

Patients with chronic pancreatitis typically present to the ED with acute exacerbations of pain or complications of their disease. The prognostic indices used for acute pancreatitis can be applied to these patients. Most patients will require admission, with over 90% of hospitalizations related to presentations for abdominal pain.

PANCREATIC CANCER

Pancreatic cancer is a particularly lethal form of cancer because it often goes undetected until the later stages. The survival rate is less than 10%, with only about 3% of patients surviving 5 years from the time of diagnosis. Most deaths are related to metastatic disease. Metastasis usually occurs within the abdomen, especially to the liver, but also to the lungs. Ampullary masses, which make up a small percentage of cases, are associated with a better prognosis (up to 50% may be successfully resected) because they tend to cause biliary obstruction, leading to earlier presentation and diagnosis.

Pancreatic cancer typically affects people older than 40 years, with a mean age of 71 years at diagnosis. Approximately 85% of cases are adenocarcinoma. About 10% are neuroendocrine tumors such as gastrinomas (Zollinger-Ellison syndrome), insulinomas, and glucagonomas. About two-thirds of pancreatic cancers occur in the head of the pancreas. Smoking is the most clearly linked risk factor for pancreatic cancer; other associations include alcohol abuse, obesity, diabetes, and chronic pancreatitis.

Clinical Features

Typical presenting symptoms include abdominal pain, back pain, anorexia, nausea, weight loss, and weakness. Tumors may cause obstruction, leading to cholestasis, jaundice, pancreatitis, or gastric outlet obstruction. Diabetes is also common. Late-onset diabetes in the setting of these symptoms is suggestive of pancreatic cancer.

The presentation of neuroendocrine tumors is related to the hormone secreted by the tumor. For example, insulinomas are associated with hypoglycemia, gastrinomas with peptic ulcers, gastroesophageal reflux disease, and diarrhea, and glucagonomas with glucose intolerance, weight loss, and dermatitis.

Diagnostic Testing

Abdominal CT with IV contrast is the recommended imaging modality for confirming the diagnosis and for guiding initial management. On CT, pancreatic carcinoma appears as an area of hypotumefaction. CT may also show secondary signs such as pancreatic duct cutoff, dilation of the pancreatic or common bile duct, atrophy, or border irregularities.

Although abdominal ultrasound is sensitive for detecting ductal dilatation, it is not sensitive enough for the diagnosis of pancreatic masses. EUS, on the other hand, may be of value in the diagnosis of pancreatic cancer. It is the most sensitive test in early disease and for masses smaller than 2 cm.

Management

Surgical resection can be curative, but is only possible in a very small subset of patients with no direct tumor extension. In patients with locally and systemically advanced disease, treatment is palliative. Chemotherapy and radiation may prolong survival to a small extent.
Treatment in the ED generally involves pain control and management of complications such as gastrointestinal bleeding, bowel obstruction, acute cholangitis, and venous thrombosis. In situations where the diagnosis of pancreatic cancer is made in the ED, the disease process may be advanced, and patients may benefit from the emergency clinician expediting their evaluation and facilitating multidisciplinary involvement in the patient’s case.

**KEY CONCEPTS**

- Acute pancreatitis represents a wide spectrum of disease, ranging from mild, short-lived disease to severe life-threatening disease with a mortality rate as high as 30%.
- Most cases of acute pancreatitis are caused by gallstones, followed closely by alcohol abuse.
- Diagnosis of acute pancreatitis relies on the presence of at least two of these three criteria—typical clinical features, serum amylase or lipase level 3 times the upper limit of normal, confirmatory imaging.
- Determining the serum lipase level is preferred over the amylase level because of its greater sensitivity and specificity.
- CT does not need to be performed routinely, but only for cases of diagnostic uncertainty or in the later phases to rule out complications.
- Following the diagnosis of pancreatitis, abdominal ultrasound should be performed early to determine if the cause is biliary.

- Treatment of acute pancreatitis is mainly supportive, with fluid resuscitation and pain control paramount. Lactated Ringer’s solution is more physiologic than normal saline and may confer better outcomes in patients receiving large volumes of fluids. There is no evidence to support one analgesic agent over another.
- Antibiotics are not indicated for prophylaxis and are not purely based on SIRS criteria, but should be given in cases of infected pancreatic necrosis or other clear evidence suggesting infection.
- ERCP is only indicated in cases of cholangitis or biliary obstruction.
- Most patients require hospitalization for symptomatic control, monitoring of hydration and nutrition status, and management of complications.
- There is no perfect scoring system to help predict severity and outcomes in pancreatitis. The most widely accepted systems include Ranson’s, APACHE-II, CTSI, and BISAP. Each has different strengths and weaknesses.

REFERENCES
elevated in normal individuals. It is likely to be as sensitive as the serum lipase level but is less specific. Increasing the cutoff value decreases the sensitivity but increases the specificity.

81.4. Which of the following statements regarding the use of radiographic studies for the evaluation of pancreatitis is true?

A. CT is indicated in pancreatitis if there is acute deterioration.
B. Oral administration of a contrast agent for abdominal CT may aggravate pancreatitis.
C. The study of choice in suspected gallstone pancreatitis is ultrasonography.
D. Ultrasonography and CT of the abdomen are equally accurate for visualizing the biliary tract.
E. Ultrasonography may help differentiate pancreatitis from pancreatic pseudocyst.

Answer: A. There is no perfect test. Ultrasonography has a sensitivity of 94% for gallstones but far less for common bile duct stones or biliary dilation, for which ERCP is the test of choice because of its sensitivity for detecting small duct stones or strictures. CT is excellent for ruling out other causes of abdominal pain (eg, pseudocyst, abscess, necrosis, vascular abnormalities, hemorrhage) and is indicated if the diagnosis is uncertain, if fever and leukocytosis are present, and with acute deterioration. Oral contrast material does not aggravate pancreatitis. A non–contrast-enhanced helical scan may also be helpful if an oral contrast agent cannot be tolerated.
Disorders of the Small Intestine*

Chad E. Roline | Robert F. Reardon

SMALL BOWEL OBSTRUCTION

Background

Small bowel obstruction (SBO) is a common problem encountered in the emergency department (ED). Advances in imaging as well as operative techniques have greatly improved the prognosis for patients with this condition and have decreased the mortality rate from nearly 60% in 1900 to less than 8% today.

Anatomy and Physiology

There are several different types of SBO. The term mechanical obstruction implies the presence of a physical barrier to the movement of the intestinal contents. Obstructions of this type can be further subclassified according to the cause of the obstruction relative to the intestinal wall (Box 82.1). Lesions external to the intestinal tract cause obstruction by compressing from outside the gut. This is usually a result of postoperative adhesions, but hernias and intraperitoneal neoplasms are other causes. Lesions intrinsic to the intestinal tuberculosis itself can cause mechanical obstruction, such as primary intestinal neoplasms, localized infection (eg, intestinal wall tuberculosis), and trauma-related conditions (eg, a hematoma of the intestinal wall). Lesions within the intestinal lumen itself can lead to obstruction, such as bezoars, ingested foreign bodies, and gallstone ileus.

Another important distinction of SBO is whether the obstruction is a simple or closed loop obstruction. A simple obstruction occurs at a single point. A closed loop–type obstruction involves obstruction at two locations, thus creating a segment of bowel with compromised blood flow proximally and distally. Closed loop obstructions are seen when a twist develops in the mesentry or, in the case of an internal hernia, when a loop of bowel becomes entrapped in a defect in the mesentery (Fig. 82.1). If not promptly recognized and relieved, a closed loop obstruction can quickly lead to intestinal infarction and necrosis, which has twice the mortality rate of simple obstructions.

In contrast to a mechanical obstruction, a neurogenic or functional obstruction occurs as a result of disruption of the normal coordinated peristaltic activity of the gastrointestinal (GI) tract in the absence of a physical blockage within the intestinal lumen. This is also commonly referred to as an adynamic ileus. The causes of adynamic ileus are listed in Box 82.2. It often occurs in patients who have undergone abdominal surgery and is transient in nature. Some degree of functional obstruction is considered normal after surgery and results from multiple factors, including an inflammatory response to intestinal manipulation, effects of analgesics, and release of hormones and neurotransmitters. In addition to surgery, a number of medical conditions can lead to a functional SBO, including infection, medications, and metabolic abnormalities.

The term pseudo-obstruction refers to a poorly understood and complex syndrome in which the signs and symptoms of mechanical obstruction, including the appearance of dilated bowel on radiography, are present in the absence of a mechanical lesion. This is thought to involve disruption of intestinal pacemaker activity controlled by a specialized group of cells found in the GI tract called the interstitial cells of Cajal (ICCs). These cells regulate the contractility of the intestinal smooth muscle and are under the influence of the enteric nervous and autonomic systems. Pathology at any one of these sites can lead to pseudo-obstruction. Causes include degenerative neuropathies, autoimmune and paraneoplastic disease, and hereditary conditions. The symptoms of pseudo-obstruction are often chronic and respond poorly to treatment.

Pathophysiology

Interruption of normal flow through the intestinal lumen triggers a cascade of physiologic changes that correlate with the progressive development of symptoms. In the presence of a mechanical obstruction, the bowel proximal to the blockage first becomes mildly dilated by the accumulation of partially digested food and normal intestinal secretions. These secretions are referred to as succus entericus and are secreted by cells lining the intestinal wall in response to mechanical stimulation. Increased intestinal dilation causes an increase in peristalsis throughout the intestines, which can trigger frequent and loose bowel movements early in the progression of the obstruction as well as episodes of nausea and vomiting. As the process continues, the bowel wall becomes edematous and the normal absorptive function of the intestinal wall decreases, leading to further accumulation of contents in the intestinal lumen proximal to the obstruction. Owing to the loss of normal intestinal motility, bacterial overgrowth begins to occur in the proximal small bowel. It is this overgrowth in a location of the intestines that is normally relatively sterile that explains the feculent nature of the emesis frequently observed in patients with SBO. As the obstruction continues, there is a transudative fluid loss into the peritoneal cavity, leading to worsening hypovolemia and dehydration. In addition, if the obstruction is proximal in location, continued bouts of emesis can lead to electrolyte abnormalities, metabolic alkalosis, severe hypovolemia, and shock.

In a closed loop obstruction, the rise in intraluminal pressure occurs much more rapidly because the intestinal contents cannot flow retrograde. Intestinal venous congestion and then arterial obstruction can also progress quickly to intestinal ischemia and infarction, referred to as a strangulation obstruction. If not promptly relieved, necrosis and intestinal perforation can occur. The resulting leakage of the intestinal contents into the peritoneum can lead to peritonitis and sepsis.

In the developed world, the most common cause of SBO is postoperative adhesions, which account for approximately 60% of cases. These adhesions develop as a result of a process involving the interaction among numerous types of cells, cytokines, and coagulation factors caused by damage to peritoneal surfaces, with a subsequent increase in fibrin formation. It has been estimated that 93% to 100% of patients who undergo transperitoneal surgery will develop postoperative adhesions, and up to 25% of them will develop a SBO. In cases of emergent laparotomy for trauma, GI tract perforation is a major independent risk factor

*The contributors would like to thank Dr. Susan P. Torrey and Dr. Philip Henneman for their work in earlier editions.
for the development of SBO while the patient is still in the hospital. Over the last several years, numerous physical bioabsorbable barriers and pharmacologic agents have been evaluated as potentially useful in decreasing the formation of postoperative adhesions.

The second most common cause of SBO is tumors, which are responsible for roughly 20% of cases. This includes malignancies, such as adenocarcinomas, carcinoid tumors, lymphomas, and sarcomas, and benign conditions, including adenomas, leiomyomas, and lipomas. In addition to these primary GI tumors, gynecologic cancers, especially ovarian cancer, are a very common cause of SBO. Metastatic disease is yet another tumor-related cause of SBO (eg, metastatic breast, skin, and testicular cancers).

Hernias are the third most common cause of SBO, found in approximately 10% of cases. Similar to their relative frequency in general, ventral and inguinal hernias are usually encountered, but femoral, parastomal, lateral ventral (also called spigelian hernia), and internal hernias may also lead to SBO. Although rare in the general population, internal hernias are a recognized complication of bariatric surgery, especially when a Roux-en-Y type procedure has been performed. In this group, internal hernias have been described in up to 5% of patients and usually develop at the mesocolic window. Another rare type of hernia is the obturator hernia. This hernia develops into the obturator foramen and is especially common in older women who have recently lost a significant amount of weight. The female pelvis is wider and the obturator canal is more oblique in women than in men. This, in combination with a loss of preperitoneal fat in older, often emaciated patients, predisposes to the development of an obturator hernia. Because an external mass is absent, the diagnosis can be especially challenging, which explains why it carries the highest mortality of any abdominal hernia, nearly 70% when it is incarcerated.

Gallstone ileus is a rare but important cause of mechanical SBO (Fig. 82.2). It is responsible for 1% to 4% of all cases of mechanical obstruction and is most frequently seen in older adults with underlying medical problems. The pathogenesis involves the entry of a gallstone into the intestinal tract through a biliary-enteric fistula. This results from the localized inflammation of cholecystitis and, in most cases, entry occurs via a choledochoduodenal fistula, although cholecystocolonic and cholecystogastric fistulae can also be involved. After entering the intestinal lumen, the gallstone migrates distally. As a stone moves through the intestinal lumen, it often increases in size as bowel content sedimentation becomes attached. Eventually, the gallstone becomes lodged, usually in the ileum, which is the narrowest segment of the small bowel, and the patient then develops symptoms of obstruction.

---

**Box 82.1**

Lesions Causing Small Bowel Obstruction Relative to the Intestinal Wall

**EXTERNAL TO INTESTINAL WALL**
- Postoperative adhesions
- Hernias
- Volvulus
- Compressing masses (tumors, abscesses, hematomas)

**INTRINSIC TO INTESTINAL WALL**
- Primary neoplasms
- Inflammatory (eg, Crohn’s disease, radiation enteritis)
- Infectious causes (eg, intestinal tuberculosis)
- Intussusception
- Traumatic (intestinal wall hematoma)
- Intraluminal
- Bezoars
- Foreign bodies
- Gallstones
- Ascaris infestation

**Box 82.2**

Causes of Adynamic Ileus

- Metabolic disease (especially hypokalemia)
- Medications (eg, narcotics)
- Infection (retroperitoneal, pelvic, intrathoracic)
- Abdominal trauma
- Laparotomy
Small bowel volvulus occurs infrequently but is a potentially catastrophic cause of SBO. This condition results from the abnormal twisting of a loop of small bowel around the axis of its own mesentery. Although it accounts for only 3% to 6% of SBO cases in the West, it is much more common in Africa, India, and the Middle East, where it is responsible for up to 20% of cases. Primary small bowel volvulus occurs in an otherwise normal abdominal cavity; secondary small bowel volvulus occurs when a congenital or acquired abnormality leads to the development of the volvulus, as in the case of intestinal malrotation or as a result of postoperative adhesions.

A reported increase in small bowel volvulus during Ramadan has been attributed to eating a large amount of food bulk after prolonged fasting, causing the proximal jejunum to descend into the pelvis, displacing empty small bowel loops upward and initiating malrotation. Alterations in gut motility and increased small bowel length have also been suggested as possible predisposing factors.

Secondary causes of small bowel volvulus include intestinal malrotation caused by the arrest of normal rotation of the embryonic gut or because of postoperative adhesions. In the case of malrotation, more than 50% of affected children present for evaluation before 1 month of age with small bowel volvulus. Because a small bowel volvulus is a classic closed loop obstruction, prompt recognition and surgical treatment are imperative because the risk of strangulation is high.

The term intussusception describes the invagination or “telescoping” of a part of the small intestine into itself. This results in the development of venous and lymphatic congestion, with consequent intestinal edema, which can lead to intestinal ischemia and perforation. Intussusception occurs in patients of all ages but is most frequently seen in children younger than 2 years. It is the most common cause of intestinal obstruction in infants 6 to 36 months of age. Unlike ileocolic intussusception, which can often be treated nonoperatively by enema reduction, surgery is more often required in cases of intussusception limited only to the small bowel. In children, the cause is usually idiopathic, but several studies have shown an association with adenovirus infection. It has been postulated that enteric adenovirus infection may trigger stimulation of the lymphatic tissue in the intestinal tract, which may create a lead point for the intestine to be dragged into itself by the normal peristaltic activity of the intestines. In contrast to the idiopathic nature of intussusception in children, a mechanical cause is found in more than 90% of adult cases. Tumors, benign or malignant, are discovered as the initiating cause in more than 65% of adult cases. Adult intussusception has been reported in association with acquired immunodeficiency syndrome (AIDS) as a result of lymphoma or unusual infections, such as atypical mycobacterial infections.

**Clinical Features**

**History**

Patients with SBO commonly report crampy abdominal pain, abdominal distention, nausea, vomiting, constipation, and/or the inability to pass flatus. The pain is often described as periumbilical in location and typically has a crescendo-decrescendo pattern. The recurrent waves of discomfort can last from seconds to minutes. In more proximal obstruction, symptoms of nausea and vomiting can be much more severe, and the onset of symptoms is often more abrupt. Distal obstructions typically cause symptoms over a slower period of 1 to 2 days and are frequently accompanied by greater abdominal distention. The colon requires up to 24 hours to empty after the formation of an SBO, and the associated small bowel distention stimulates peristalsis; consequently, flatus and the passage of stool may continue, even in the presence of a complete obstruction. A history of previous obstructions as well as a thorough past surgical history should be obtained, and any history of malignancy or inflammatory bowel disease should be elicited. The use of medications (especially narcotics) that may affect bowel function should be reviewed.

**Physical Examination**

The physical examination starts with a careful evaluation of the patient’s hemodynamic status, degree of distress, and general condition. Thus, patients requiring resuscitation can be quickly identified, and the appropriate interventions, including intravenous (IV) fluids, can be initiated early. Inspection of the patient includes a careful search for abdominal distention and hernias and should include a genital examination. Although bowel sounds in SBO are frequently described as high-pitched and tinkling in nature, studies have shown that they are also frequently decreased or absent. One study has shown that physicians listening to recordings of bowel sounds were able to identify SBO correctly in only 42% of affected patients.

The presence of peritoneal signs usually indicates late obstruction with complications, including strangulation. However, abdominal palpation in the setting of bowel dilation can give the false impression of peritonitis, because quick compression-decompression of dilated bowel may elicit a pain response. For this reason, it may be helpful to determine the presence of pain with cough or gentle shaking of the patient’s pelvis to investigate for true peritonitis better.

**Differential Diagnosis**

The diagnosis of SBO should be considered in any patient with abdominal pain and vomiting, especially if there is a history of prior abdominal surgery. It may be difficult to differentiate SBO from nonobstructive intestinal motility disorders, such as adynamic ileus or intestinal pseudo-obstruction, by history and physical examination alone.

Other conditions to consider in the differential diagnosis include gastroenteritis, mesenteric adenitis, constipation, cholecystitis or nephrolithiasis, ectopic pregnancy, pancreatitis, peptic ulcer disease, atypical myocardial infarction, leaking abdominal aortic aneurysm (AAA), and mesenteric ischemia. These pathologies have typical signs, symptoms, and diagnostic findings that can help differentiate them from one another and from SBO, but this may be challenging, especially early in the course of the particular disorder.

**Diagnostic Testing**

**Laboratory**

Although laboratory tests are not helpful in diagnosing the presence of SBO, they can be useful in assessing the degree of dehydration and metabolic disruption resulting from the obstruction. Studies have evaluated the use of lactate and creatinine phosphokinase to identify strangulation complicating SBO. Intestinal fatty acid binding protein, which is released by necrotic enterocytes, has also been studied in an attempt to identify strangulation. Unfortunately, all the biomarkers studied to date may be normal until very late in the process of intestinal strangulation. While recognizing this, an elevated lactate level should increase the clinical suspicion for strangulation.

**Imaging**

Traditionally, plain film radiographs have been the initial imaging test of choice in the diagnosis of SBO. Abdominal plain film
CHAPTER 82 Disorders of the Small Intestine

However, the improved resolution of newer scanning devices has made this modality more attractive and an exciting area of exploration in the diagnosis of SBO. Typical ultrasound findings in SBO include fluid-filled bowel with dilated loops greater than 2.5 cm in diameter with decreased or absent peristalsis with proximally collapsed bowel (Fig. 82.4). Abdominal free fluid between loops of dilated bowel (the tanga sign) is suggestive of a high-grade obstruction.

In summary, although the benefits of plain radiographs include rapid acquisition and lower radiation, they are diagnostic in only 50% to 60% of SBOs. Ultrasound is quickly emerging as a potentially very useful tool in the diagnosis of SBO, but further research is needed.

Historically ultrasound had limited value for evaluating SBO due to the significant artifact caused by gas within the GI tract.

Computed tomography (CT) has become an increasingly popular imaging modality for the evaluation of SBO and has become the gold standard for imaging in suspected SBO. CT detects SBO with a high degree of sensitivity and specificity. In addition, unlike plain films, CT scans provides more information about the cause of obstruction, such as a tumor. More important acutely, unlike plain radiographs, CT scans are very sensitive for detecting strangulation, with a specificity of 96% and likelihood ratio of 9.3. According to the American College of Radiology Appropriateness Criteria, the CT scan of choice for the evaluation of a suspected high-grade bowel obstruction is a scan of the abdomen and pelvis with IV contrast and without oral contrast. This guideline states that “oral contrast will not reach the site of obstruction, wastes time, adds expense, can induce further patient discomfort, will not add to diagnostic accuracy, and can lead to complications, particularly vomiting and aspiration.”

However, the improved resolution of newer scanning devices has made this modality more attractive and an exciting area of exploration in the diagnosis of SBO. Typical ultrasound findings in SBO include fluid-filled bowel with dilated loops greater than 2.5 cm in diameter with decreased or absent peristalsis with proximally collapsed bowel (Fig. 82.4). Abdominal free fluid between loops of dilated bowel (the tanga sign) is suggestive of a high-grade obstruction.

In summary, although the benefits of plain radiographs include rapid acquisition and lower radiation, they are diagnostic in only 50% of SBOs. Ultrasound is quickly emerging as a potentially very useful tool in the diagnosis of SBO, but further research is needed.

Computed tomography (CT) has become an increasingly popular imaging modality for the evaluation of SBO and has become the gold standard for imaging in suspected SBO. CT detects SBO with a high degree of sensitivity and specificity. In addition, unlike plain films, CT scans provides more information about the cause of obstruction, such as a tumor. More important acutely, unlike plain radiographs, CT scans are very sensitive for detecting strangulation, with a specificity of 96% and likelihood ratio of 9.3. According to the American College of Radiology Appropriateness Criteria, the CT scan of choice for the evaluation of a suspected high-grade bowel obstruction is a scan of the abdomen and pelvis with IV contrast and without oral contrast. This guideline states that “oral contrast will not reach the site of obstruction, wastes time, adds expense, can induce further patient discomfort, will not add to diagnostic accuracy, and can lead to complications, particularly vomiting and aspiration.”

Historically ultrasound had limited value for evaluating SBO due to the significant artifact caused by gas within the GI tract. However, the improved resolution of newer scanning devices has made this modality more attractive and an exciting area of exploration in the diagnosis of SBO. Typical ultrasound findings in SBO include fluid-filled bowel with dilated loops greater than 2.5 cm in diameter with decreased or absent peristalsis with proximally collapsed bowel (Fig. 82.4). Abdominal free fluid between loops of dilated bowel (the tanga sign) is suggestive of a high-grade obstruction.

In summary, although the benefits of plain radiographs include rapid acquisition and lower radiation, they are diagnostic in only 50% of SBOs. Ultrasound is quickly emerging as a potentially very useful tool in the diagnosis of SBO, but further research is needed.

to clarify its role. Abdominal and pelvis CT scanning with IV contrast currently remains the preferred imaging test of choice because it is the most sensitive and specific test for detecting SBO and is the most likely to identify both the cause and complications of the obstruction (specifically strangulation) with a high degree of sensitivity.

Management

Hemodynamically unstable patients should be resuscitated with crystalloid solution via a large-bore catheter. Findings suggestive of bowel strangulation should prompt rapid surgical consultation. Although many emergency clinicians and surgeons consider the use of nasogastric decompression to be dogma, its effect in decreasing the duration of SBO has scant support in the medical literature. In the era of modern antiemetics, in the setting of a simple SBO due to adhesions, if the patient’s symptoms of nausea and vomiting can be controlled with medication (e.g., ondansetron 4 mg IV every 6 to 8 hours or metoclopramide, 10 mg IV every 6 to 8 hours), it may be reasonable to delay nasogastric tube insertion. However, if symptoms persist or if the patient has an altered level of consciousness placing him or her at risk for aspiration, a nasogastric tube should be promptly inserted and attached to wall suction. There is no benefit to the use of long intestinal tubes instead of a traditional nasogastric tube. Placement of a nasogastric tube is a noxious procedure, and attempts should be made to anesthetize the patient’s nasopharynx with topical anesthetic before insertion.

There are numerous serious complications associated with SBO. Persistent vomiting can lead to hypovolemia, metabolic alkalosis, and shock. If strangulation occurs, necrosis of the bowel can lead to perforation, and leakage of contaminated bowel contents into the peritoneal space can cause peritonitis, intra-abdominal abscess formation, and sepsis. As one would expect, complications are more common in older adults and those with comorbidities. There are also several potential complications related to surgical intervention for SBO, including wound infection and short bowel syndrome. Unfortunately, in addition to these adverse effects, the rate of recurrence of SBO is high—40% for patients treated nonoperatively and 27% for those treated operatively. For patients with SBO secondary to adhesions, the relative risk of recurrence increases with the number of prior episodes of obstruction. For those with four or more episodes of adhesional SBO, the recurrence rate is more than 80%.

There is no convincing evidence to recommend the empirical use of antibiotics for the nonoperative management of a simple SBO. In patients in whom surgical exploration is planned or perforation is suspected, antibiotics are recommended and should provide coverage against the gram-negative and anaerobic organisms that colonize the intestinal tract (e.g., a second-generation cephalosporin such as cefuroxime, 1000 mg IV tid, or a broad-spectrum carbapenem such as meropenem, 1000 mg IV tid).

SBO in the presence of known malignancy is very common, occurring in up to 30% of patients with colon cancer and in 50% of patients with ovarian cancer at some time in the course of their disease. Patients who do not qualify for surgical intervention because of intra-abdominal carcinomatosis, massive ascites, or poor overall health status can be treated with self-expanding metal stents and the use of octreotide, 0.3 mg/day, given over three doses or as a continuous infusion to reduce GI secretions rapidly, may provide palliative relief. A collaborative approach with the patient’s oncologist and consulting surgeon can provide the ideal individualized treatment for the patient in this situation. In the setting of terminal metastatic disease, although surgery may provide temporary symptomatic improvement, it often comes at the cost of a significant proportion of the patient’s remaining days being spent in the hospital.

Disposition

Patients with SBO merit admission to the hospital. Many simple SBOs related to adhesions will resolve with conservative treatment in the next 48 to 72 hours. In case of a partial SBO, in which initial imaging suggests that some colonic contents can pass the obstruction, some surgical guidelines suggest administration of a watersoluble contrast medium at admission or after 48 hours of failed conservative treatment. Appearance of contrast in the colon within 24 hours of administration predicts nonoperative resolution of the obstruction.3,4 One study has found that patients with SBO admitted to a surgical service for inpatient management had a shorter length of stay, lower hospital charges, and lower mortality than those admitted to a medical service.5 This was attributed largely to the fact that patients for whom conservative management was failing and needed surgical intervention were identified earlier when being managed primarily by the surgical team. Regardless of admitting service, patients with SBO need frequent reassessment to determine disease progression or resolution. Finally, although laparoscopic surgery was once considered inappropriate for the management of SBO, there has been a growing experience with its successful use in patients with SBO, particularly those with obstructions caused by adhesions.6

ACUTE MESENTERIC ISCHEMIA

Background

Acute mesenteric ischemia involves the sudden reduction or loss of blood flow to the small bowel and may also involve the right colon. The left colon has a much higher degree of collateral blood flow and is less prone to mesenteric ischemia. When acute mesenteric ischemia occurs, rapid intestinal injury results. This condition should be clearly differentiated from chronic mesenteric ischemia (CMI), also referred to as intestinal angina, which often manifests as recurrent episodes of abdominal pain resulting from insufficient intestinal blood flow during periods of increased postprandial metabolic demand. CMI does not usually require emergent therapy; however, it is also possible for acute mesenteric ischemia to develop in these patients.

Overall, acute mesenteric ischemia is a rare clinical problem. There are four specific clinical categories that make up the overwhelming majority of causes, each with distinct epidemiologic risk factors—mesenteric arterial embolus, mesenteric arterial thrombosis, nonocclusive mesenteric ischemia, and mesenteric venous thrombosis. Despite significant advances in the understanding of the pathophysiology, the mortality rate has remained as high as 60 to 80%, and the diagnosis and treatment of this vascular catastrophe have remained difficult.

Anatomy and Physiology

The mesenteric vessels arise from the primitive ventral segmental arteries. Although there is considerable individual variability, these vessels typically regress as embryologic development proceeds, with the exception of the 10th, 13th, and 21st segmental arteries. These become the celiac trunk, superior mesenteric artery (SMA), and inferior mesenteric artery (IMA), respectively. The celiac trunk arises from the anterior aspect of the abdominal aorta and branches into the common hepatic, splenic, and left gastric arteries. These vessels supply the distal esophagus to the duodenum at the entrance of the bile duct. The SMA normally arises 1 cm below the celiac trunk and runs toward the cecum, terminating as the ileocolic artery. The SMA supplies the distal half of the duodenum to the proximal two-thirds of the transverse colon. The IMA originates approximately 6 to 7 cm below the SMA and gives rise to the left colic artery, sigmoid arteries, and
Gross Coronal in Note Fig. 82.5. Median age of patients with mesenteric arterial emboli is 70 years, ischemia, are responsible for approximately 50% of cases. The arterial emboli, the most common cause of acute mesenteric ischemia, result in multiorgan failure and rapid death.

Cytokines and toxic oxygen radicals caused by reperfusion, which point results in the systemic release of several proinflammatory cytokines and toxic oxygen radicals caused by reperfusion, which causes mesenteric vasoconstriction. Hormonal influences include the direct action of angiotensin II released as a result of mucosal ischemia. These metabolites then diffuse to the local arterioles, triggering relaxation in the smooth muscle and increased blood flow, thereby allowing for efficient adjustments to the intestinal blood supply. Smooth muscle relaxation can also be brought about directly by a decrease in the perfusion pressure in the arterioles themselves. These two mechanisms are referred to as the metabolic and myogenic pathways. Intestinal blood flow is also controlled extrinsically through neural and hormonal mechanisms. Increased sympathetic tone to the paired celiac ganglia located adjacent to the celiac trunk results in mesenteric and arteriolar vasoconstriction. Hormonal influences include the direct action of angiotensin II released as a result of decreased extracellular volume, as well as vasopressin, which causes mesenteric vasoconstriction.

Pathophysiology

Although these mechanisms allow for the mesenteric circulation to adapt to wide variations in the metabolic needs of the gut and systemic perfusion, the bowel is very quickly injured in the setting of acute compromise. Because of the high metabolic demands of the intestinal mucosa, structural damage to the intestinal villi can be observed histologically within 15 minutes of absolute ischemia. If not corrected, mucosal sloughing occurs within 3 hours. By 6 hours, transmural necrosis is complete (Fig. 82.5). Complicating the situation even further, reestablishment of blood flow at this point results in the systemic release of several proinflammatory cytokines and toxic oxygen radicals caused by reperfusion, which can lead to multiorgan failure and rapid death.

Mesenteric Arterial Embolism

Arterial emboli, the most common cause of acute mesenteric ischemia, are responsible for approximately 50% of cases. The median age of patients with mesenteric arterial emboli is 70 years, and two-thirds are women. Emboli are usually cardiac in origin and arise from left atrial or ventricular mural thrombi or valvular lesions. Risk factors for the development of such thrombi include myocardial ischemia or infarction, cardiomyopathies, ventricular aneurysms, endocarditis, and atrial dysrhythmias, specifically atrial fibrillation. Compared with the estimated annual risk of stroke of 2.3%, the annual risk of AMI caused by thromboembolism secondary to atrial fibrillation is 0.14%. The SMA is most frequently affected because of the large caliber of the vessel and its narrow takeoff angle from the aorta. The embolus typically lodges 3 to 10 cm distal to the origin of the SMA (Fig. 82.6). The jejunum is most often involved, as it is distant from the collateral flow provided from the celiac and inferior mesenteric arteries.

Mesenteric Arterial Thrombosis

Mesenteric arterial thrombosis results from the progression of atherosclerotic disease of the mesenteric vasculature. Risk factors for development include advanced age, hypertension, diabetes, and tobacco use. Affected patients frequently have a history suggestive of CMI of several months’ or years’ duration. Unlike embolic occlusions, thrombosis usually occurs in the proximal SMA at the origin of the vessel.

Nonocclusive Mesenteric Ischemia

Nonocclusive mesenteric ischemia occurs as a result of mesenteric vasospasm in the absence of a physical obstruction. This vasospasm is triggered by mesenteric hypoperfusion or excessive sympathetic nervous system activity. Mesenteric hypoperfusion can result from a wide variety of conditions, including sepsis, severe dehydration, pancreatitis, or hemorrhagic shock. Excessive sympathetic activity can result from congestive heart failure, or the use of medications and drugs such as vasopressors, cocaine, or digoxin. Once initiated, this vasospasm often persists even after correction of the underlying condition, and repeated episodes of ischemia and reperfusion occur. Studies suggest that this recurrent pattern of ischemia and reperfusion may result in more severe histologic injury than a single episode of prolonged ischemia.

Mesenteric Arterial Embolism

Arterial emboli, the most common cause of acute mesenteric ischemia, are responsible for approximately 50% of cases. The median age of patients with mesenteric arterial emboli is 70 years, and two-thirds are women. Emboli are usually cardiac in origin and arise from left atrial or ventricular mural thrombi or valvular lesions. Risk factors for the development of such thrombi include myocardial ischemia or infarction, cardiomyopathies, ventricular aneurysms, endocarditis, and atrial dysrhythmias, specifically atrial fibrillation. Compared with the estimated annual risk of stroke of 2.3%, the annual risk of AMI caused by thromboembolism secondary to atrial fibrillation is 0.14%. The SMA is most frequently affected because of the large caliber of the vessel and its narrow takeoff angle from the aorta. The embolus typically lodges 3 to 10 cm distal to the origin of the SMA (Fig. 82.6). The jejunum is most often involved, as it is distant from the collateral flow provided from the celiac and inferior mesenteric arteries.

Mesenteric Arterial Thrombosis

Mesenteric arterial thrombosis results from the progression of atherosclerotic disease of the mesenteric vasculature. Risk factors for development include advanced age, hypertension, diabetes, and tobacco use. Affected patients frequently have a history suggestive of CMI of several months’ or years’ duration. Unlike embolic occlusions, thrombosis usually occurs in the proximal SMA at the origin of the vessel.

Nonocclusive Mesenteric Ischemia

Nonocclusive mesenteric ischemia occurs as a result of mesenteric vasospasm in the absence of a physical obstruction. This vasospasm is triggered by mesenteric hypoperfusion or excessive sympathetic nervous system activity. Mesenteric hypoperfusion can result from a wide variety of conditions, including sepsis, severe dehydration, pancreatitis, or hemorrhagic shock. Excessive sympathetic activity can result from congestive heart failure, or the use of medications and drugs such as vasopressors, cocaine, or digoxin. Once initiated, this vasospasm often persists even after correction of the underlying condition, and repeated episodes of ischemia and reperfusion occur. Studies suggest that this recurrent pattern of ischemia and reperfusion may result in more severe histologic injury than a single episode of prolonged ischemia.

Mesenteric Arterial Embolism

Arterial emboli, the most common cause of acute mesenteric ischemia, are responsible for approximately 50% of cases. The median age of patients with mesenteric arterial emboli is 70 years,
Mesenteric Venous Thrombosis

Mesenteric venous thrombosis is the least common cause of acute mesenteric ischemia (AMI), accounting for only 5% to 15% of all mesenteric ischemic events. It usually involves the superior mesenteric vein and its branches (Fig. 82.7). In the vast majority of cases (>75%), an underlying inherited thrombotic disorder or inherited or acquired hypercoagulable state can be identified. The most common cause is factor V Leiden thrombophilia, which is thought to account for 20% to 40% of cases. Other inherited prothrombotic states implicated in the development of mesenteric venous thrombosis include deficiency in antithrombin III, protein C, or protein S. Hematologic conditions predisposing to this condition include polycythemia vera and essential thrombocythemia. Oral contraceptive use accounts for 9% to 18% of the episodes of mesenteric venous thrombosis in young women. Local intra-abdominal inflammation secondary to pancreatitis, malignancy, or inflammatory bowel disorders also increases the risk of mesenteric venous thrombosis. Finally, the venous stasis caused by portal hypertension is a recognized risk factor.

Box 82.3 summarizes causes of mesenteric venous thrombosis.

Unusual Causes of Mesenteric Ischemia

In addition to the conditions already described, there are numerous case reports of unusual causes of mesenteric ischemia. These include SMA dissection leading to occlusion, tumor emboli, retroperitoneal fibrosis, and various types of vasculitis, including Buerger’s disease, polyarteritis nodosa, and Takayasu’s arteritis. Because these conditions involve a rare cause of an already rare condition, they frequently go unrecognized until patients develop major adverse effects.

Clinical Features

History

The history at presentation of mesenteric ischemia is largely dependent on the nature of the underlying cause. The traditional historical triad of acute mesenteric ischemia is the sudden onset of poorly localized abdominal pain and gastric emptying (vomiting or diarrhea) in a patient with cardiac disease. This is especially true in cases of SMA embolism or thrombosis, in which symptoms and clinical deterioration can rapidly occur. In cases of mesenteric venous thrombosis, the symptoms are slower in onset and often have been present for several days by the time the patient seeks medical attention. Approximately one-third of patients with acute embolic mesenteric ischemia and 50% of patients with acute mesenteric venous thrombosis have a personal history of an embolic event, such as a pulmonary embolism, deep vein thrombosis, or ischemic stroke. Patients with nonocclusive mesenteric ischemia are often already critically ill and in the hospital, making it difficult or impossible for them to provide historical details to the treating physician.

Physical Examination

The pain in acute mesenteric ischemia is typically described as being out of proportion to the physical examination findings. The patient may be writhing in pain but have a soft abdomen without guarding, especially early in the course of the event, when only the visceral structures are ischemic. As the parietal peritoneum becomes ischemic, the abdominal physical findings progress. If the ischemia progresses to infarction, peritonitis may be present. Heme-positive stools may also be noted. Hypotension, tachycardia, and tachypnea are all signs of severe ischemia and suggest a poor prognosis.

Differential Diagnosis

Other potentially devastating conditions to consider in the differential diagnosis of acute-onset severe abdominal pain include leaking AAA, perforated viscus, bowel obstruction, biliary disease, and atypical myocardial infarction.
Diagnostic Testing

Laboratory Tests

Initial laboratory results in patients with acute mesenteric ischemia are often nonspecific and may include leukocytosis, an elevated hematocrit secondary to hemoconcentration, and metabolic acidosis. Several serum biomarkers have been investigated as early indicators including lactate, D-dimer, interleukin (IL)-6, and serum ischemia-modified albumin levels. A meta-analysis has shown a pooled sensitivity of 86% and pooled specificity of 42% for lactate, and a pooled sensitivity of 96% and a pooled specificity of 40% for D-dimer. To date, no biomarkers have been found that are sufficiently sensitive and specific to diagnose or eliminate mesenteric ischemia based on laboratory results alone. Recognizing these limitations, when considering this diagnosis, the serum lactic acid level is currently the most useful laboratory test available. In addition to its wide availability and rapid turnaround time, the short half-life of serum lactate (=20 minutes) may be useful for the emergency clinician to allow for serial measurements, especially early in the course of suspected acute mesenteric ischemia.

Imaging

Plain abdominal radiographs in mesenteric ischemia are usually nonspecific. Later in the disease course, plain radiographic findings may show so-called thumbprinting, in which multiple, round, smooth soft tissue densities project into the intestinal lumen because of mucosal and submucosal edema and hemorrhage. More specific but very late plain radiographic findings indicating infarction include pneumatosis intestinaIs and portal venous gas.

Mesenteric angiography remains the gold standard in the radiographic evaluation for mesenteric ischemia and offers the benefit that diagnosis and initial treatment can occur concurrently. However, angiographic services are often not readily available on a routine basis. As a result, CT angiography has largely replaced conventional angiography as the initial imaging study of choice for the evaluation of mesenteric ischemia. Several studies have shown that with the emergence of multidetector scanners, the sensitivity and specificity for mesenteric ischemia are high, approximately 94% and 96%, respectively.

Duplex sonography has been found to be very specific (92%–100%) for the detection of AMI, but its sensitivity is decreased (70%–89%) by limited evaluation beyond the proximal main vessel. It is also unable to provide much information about complications of acute mesenteric ischemia, including bowel infarction.

Management

Once AMI has been diagnosed, the goals of treatment are to restore mesenteric blood flow as rapidly as possible, manage underlying conditions, treat persistent mesenteric vasospasm if present, and mitigate the risk of further clot propagation. Initial interventions should focus on fluid resuscitation and hemodynamic stabilization. Because these patients are often older adults with cardiac comorbidities, invasive monitoring may be indicated. If vasopressors are required, dobutamine, low-dose dopamine, or milrinone are recommended, because these have been shown to have less of a vasoconstrictive effect on the mesenteric vasculature than other agents. With evidence of infarction, perforation, or peritonitis, antibiotics suitable for enteric coverage, such as ceftriaxone, 1g IV qd, or ciprofloxacin 500 mg qd, with either in combination with metronidazole, 500 mg IV tid, are recommended, and a surgeon should be promptly consulted. Further management depends on the cause of ischemia, and controversies exist about the optimal management of these critically ill patients.

Regardless of cause, if signs of intestinal infarction or perforation with peritonitis are present, prompt emergent laparotomy is warranted. Preoperative conventional angiography may be beneficial to attempt rapid revascularization, and studies have suggested that initial endovascular revascularization may significantly improve patient outcomes and dramatically alter the future treatment of AMI. Numerous reports have detailed the use of thrombolytic agents, angioplasty, embolectomy, or vascular stenting to restore mesenteric blood flow. In addition, the phosphodiesterase inhibitor papaverine may be continuously infused directly into the compromised vessel. This agent results in elevated levels of cyclic adenosine monophosphate (cAMP), which results in profound smooth muscle relaxation. Because cAMP undergoes over 90% first-pass hepatic metabolism, few systemic effects are noted when it is infused directly into the mesenteric circulation.

Primary treatment of nonocclusive mesenteric ischemia involves interventions to reverse the underlying cause and consideration for papaverine infusion via angiographic catheter, as well as IV heparin to prevent thrombosis in the vasospastic vessel. Papaverine infusion is often maintained for 24 hours, at which time angiography may be repeated to evaluate for the resolution of vasospasm. If peritoneal signs develop, laparotomy is indicated. If the underlying medical condition persists, the mortality of nonocclusive mesenteric ischemia remains high.

The treatment of mesenteric venous thrombosis is unique in that in the absence of peritoneal findings, initial treatment with heparin infusion alone may be adequate. However, if peritoneal findings are present or develop later in the patient’s hospital course, bowel necrosis is likely, and prompt laparotomy is indicated. If the patient recovers, long-term anticoagulation with warfarin usually is provided to prevent recurrence. An appropriate evaluation for hypercoagulable conditions should be undertaken.

Even with prompt recognition and treatment of acute mesenteric ischemia, a complicated course is expected. Secondary reperfusion injury is common, and bowel initially identified as viable may progress to necrosis. Other complications include wound infections, sepsis, and pneumonia. Given the population in which AMI tends to occur, the physiologic stress of this disease process also places patients at high risk for myocardial infarction, renal failure, and pulmonary embolism while in the hospital.

Disposition

All patients with acute mesenteric ischemia require admission to the intensive care unit.
Small Bowel Obstruction

- The most common cause of SBO is postoperative adhesions. Other common causes include neoplasm and hernias.
- Abdominal CT with IV contrast is the gold standard for imaging in cases of suspected SBO. It is sensitive and specific and provides information about the cause of the obstruction and potential complication of strangulation.
- Bedside ultrasound for SBO may be a potentially useful imaging modality, but more research is needed.
- Many patients with SBO will improve with nonoperative conservative treatment; however, prompt surgical exploration is recommended when there is suspected bowel strangulation.
- Antibiotics are not indicated in cases of simple SBO.
- The recurrence rate for SBO is high, regardless whether treatment is operative or nonoperative.

Acute Mesenteric Ischemia

- Acute mesenteric ischemia (AMI) is a rare vascular catastrophe, with a very high mortality.
- AMI should be considered in patients older than 50 years with a history of cardiac disease who have acute abdominal pain, which may initially appear severe and out of proportion to physical examination findings.
- Within the diagnosis of AMI are four distinct clinical entities with specific associated risk factors, clinical presentations, and treatments—mesenteric arterial embolism, mesenteric arterial thrombosis, nonocclusive mesenteric ischemia, and mesenteric venous thrombosis.
- Although no current laboratory test has sufficient sensitivity or specificity to diagnose acute mesenteric ischemia alone, determination of the serum L-lactate level is currently the most useful.
- CT angiography is the initial imaging test of choice for the evaluation of suspected AMI.
- Successful management of acute mesenteric arterial embolism and thrombosis frequently requires multispecialty, care including general or vascular surgery, interventional radiology, and critical care, with the goal of restoring mesenteric blood flow as quickly as possible.
- Unlike cases of arterial embolism or thrombosis, in the absence of peritonitis, mesenteric venous thrombosis is often successfully managed with heparin alone.
REFERENCES

CHAPTER 82: QUESTIONS & ANSWERS

82.1. What is the most common cause of small bowel obstruction in the developed world?
A. Gallstone ileus
B. Hernias
C. Intussusception
D. Postoperative adhesions
E. Tumors

Answer: D. Although rare in the general population, internal hernias are a recognized complication of bariatric surgery, especially when a Roux-en-Y type procedure has been performed. Because of the closed loop nature of an internal hernia, they are not suitable for conservative management and require surgical intervention.

82.2. Which of the following patients are at the highest risk of developing an obturator hernia?
A. 2-year-old boy with no known medical problems
B. 45-year-old woman with a 1-year history of hysterectomy
C. 67-year-old man with a history of metastatic prostate cancer
D. 80-year-old woman with a 3-month history of rapid weight loss

Answer: D. This type of hernia is especially common in older women who have recently lost a significant amount of weight. The female pelvis is wider, and the obturator canal is more oblique in women who have recently lost a significant amount of weight. This, in combination with a loss of preperitoneal fat, predisposes to its development. Because an external mass is absent, diagnosis is especially challenging and explains why it carries the highest mortality of any abdominal hernia, at nearly 70% when incarcerated.

82.3. A 55-year-old woman with a history of Roux-en-Y gastric bypass surgery presents with a 1-day history of worsening colicky abdominal pain and vomiting. A CT scan reveals an internal hernia. What is the most appropriate disposition?
A. Administer broad-spectrum antibiotics and admit to the medicine floor.
B. Arrange for barium swallow with small bowel follow-through
C. Insert nasogastric tube and admit to the medicine floor.
D. Prompt surgical consultation and preparation for surgery should occur.

Answer: D. Prompt surgical consultation and preparation for surgery should occur.

82.4. What is the length of time from acute absolute ischemia of the intestines to completion of transmural necrosis?
A. 15 minutes
B. 60 minutes
C. 2 hours
D. 6 hours
E. 24 hours

Answer: E. The treatment of mesenteric venous thrombosis is unique in that in the absence of peritoneal findings, initial treatment with heparin alone may be adequate. In the vast majority of cases (>75%) an underlying inherited or acquired hypercoagulable state can be identified. Oral contraceptive use accounts for 9% to 18% of cases in young women.

82.5. A 35-year-old woman who currently smokes while taking oral contraceptive pills presents with 2 days of progressively worsening diffuse abdominal pain without peritoneal findings on examination. A CT scan reveals mesenteric venous thrombosis. What is the next most appropriate step?
A. Arrange for formal mesenteric venous angiography to confirm and treat.
B. Arrange for immediate exploratory laparotomy regardless of current clinical status, given the high risk of severe complications.
C. Discharge home because this will resolve without intervention.
D. Institute pain control and admit to the floor.
E. Start anticoagulation with therapeutic dosing of heparin.

Answer: E. The treatment of mesenteric venous thrombosis is unique in that in the absence of peritoneal findings, initial treatment with heparin alone may be adequate. In the vast majority of cases (>75%) an underlying inherited or acquired hypercoagulable state can be identified. Oral contraceptive use accounts for 9% to 18% of cases in young women.
Acute Appendicitis

Michael Alan Cole  |  Robert David Huang

CHAPTER 83

**PRINCIPLES**

**Background**

The appendix was once considered a vestigial organ; however, it is currently theorized that it serves as a repository for commensal bacteria that assist in normal digestive processes and may allow for recolonization of intestinal flora in times of enteric bacterial destruction. Phylogenetic studies have supported the appendix as likely having a so-called positive fitness value during mammalian evolution, whereas recent clinical research studies have demonstrated a possible increased risk of clostridial infections in patients who have had prior appendectomies.1-3

Appendicitis is the most common cause of acute abdominal pain requiring operative intervention in patients younger than 50 years. It is the most common nonobstetric abdominal emergency in pregnant females, usually occurring in the second trimester. Risk factors for appendicitis include white ethnicity, male gender, and young age (69% of cases occur in patients <30 years). Although males have an increased risk of having appendicitis (1.4:1), females have an almost twofold increased risk of undergoing appendectomy, which is partially related to the fact that women have gynecologic conditions that frequently mimic appendicitis.

**Anatomy and Physiology**

The vermiform appendix is a blind-ended tube that originates from the cecum, approximately 3 cm from the ileocecal valve. It is considered part of the cecum and has the same histologic arrangement as the large intestine. A unique aspect of the appendix is the large masses of lymphoid tissue in the mucosa and submucosa. Although it has an average length of 8 to 10 cm, the appendix may be more than 20 cm in length, thereby allowing it to traverse into the left lower or right upper quadrants of the abdomen. The average diameter of the appendix ranges from 6 to 11 mm; thus, appendiceal diameter alone, in the absence of other radiologic findings, often does not imply appendicitis. Finally, a normal appendix has an average wall thickness of 1.5 mm.

The appendix maintains afferent sensory fibers that follow the sympathetic innervation and enter the spinal cord at the 10th thoracic level (T10). It is these nerves that carry the sensation of pain and result in the periumbilical discomfort associated with early appendicitis.

There are three important anatomic features of the appendix that determine the site of the patient’s pain and tenderness when the organ is inflamed: (1) the location of the origin of the appendix off the cecum; (2) the course the appendix takes from this origin; and (3) the length of the appendix (as described above; Fig. 83.1). All these features are variable, resulting in a wide range of symptoms and signs, which often creates difficulty with the clinical diagnosis of appendicitis. Although the location of the origin of the appendix is generally thought to be positioned at McBurney’s point (exactly between an 1.5 to 2 inches from the right anterior superior iliac spine on a straight line drawn to the umbilicus), the base may be as much as 10 cm away from this site. In fact, only 40% of patients have the base of their appendix within 3m of McBurney’s point, with 36% of patients having the base more than 3m away. Next, there is significant variation involving the course of the appendix from its cecal origin. The frequency with which the appendix is found in various locations is illustrated in Fig. 83.2. Finally, in rare cases, patients may present with left lower quadrant pain or right flank pain due to a very long appendix traveling into the left lower abdomen or a retrocecal location extending into the retroperitoneum, respectively.

**Pathophysiology**

The cause of appendicitis is rooted in obstruction of the appendiceal lumen. The underlying pathophysiology is progressive in nature and best understood in a stepwise fashion—appendiceal obstruction prevents egress of mucus and bacteria from the appendix; continued mucus production and bacterial proliferation result in luminal distention, which stimulates the T10 visceral afferent nerves, creating periumbilical pain typically lasting 4 to 6 hours. Intraluminal pressure eventually exceeds local capillary pressure in the appendiceal wall, preventing arterial perfusion and resulting in tissue ischemia and inflammation; ischemia and inflammation compromise the integrity of the appendiceal wall bacteria and then invade the appendiceal wall. This causes transmural inflammation that extends into the surrounding tissues (peritoneal, ileocecal, and pelvic areas), resulting in somatic localized pain, typically focused in the right lower quadrant. If this process continues, the appendix becomes necrotic and perforates, releasing enteric contents into the peritoneum and resulting in peritonitis and, typically, diffuse abdominal pain. The length of time from the onset of symptoms to perforation is highly variable.

Although obstruction of the appendiceal lumen is thought to be a common inciting factor in appendicitis, the cause of this obstruction is variable and, in many cases, a source of obstruction is not discovered on imaging or pathology. Fecaliths (hard stools) are the most common cause of obstruction in nonperforated appendicitis (65%), followed by appendicoliths (calcified deposits) and lymphoid hyperplasia (primary or secondary to an enteric infection). Other causes of obstruction are rare; these include fecal stasis, foreign bodies (eg, vegetable matter, inspissated barium), tumors, and intestinal parasites.

There are two additional pathologic processes associated with appendicitis. First, so-called tip appendicitis is appendiceal inflammation localized to the distal end of the appendix. The clinical significance of this disorder is that it may be missed on imaging due to the limited extent of disease and the lack of classic findings associated with appendicitis; it has been demonstrated to contribute to the false-negative rate associated with computed tomography (CT) imaging. Second, stump appendicitis is a very rare entity that results from inflammation of the appendiceal remnant that may persist after the appendix has been removed surgically. Timing of its occurrence varies; it has been diagnosed
between 4 days and up to 50 years after the initial appendectomy.7

**CLINICAL FEATURES**

Typical presentations of appendicitis often allow an experienced provider to hone in on a diagnosis in a rather rapid fashion; unfortunately, typical findings are the exception and not the rule. For historical purposes, the constellation findings classically associated with acute appendicitis include younger age, epigastric pain that migrates to the right lower quadrant (RLQ), and tenderness of the RLQ. However, the combination of these findings occurs in less than 50% of patients with acute appendicitis thus limiting their use in clinical decision making.4 Missed acute appendicitis is one of the most common causes of litigation surrounding emergency medicine, which speaks to the challenges in diagnosing this illness in the presence of often ambiguous symptoms.5

No one element of the history or physical examination can reliably be used to diagnose or exclude appendicitis. Therefore, focusing on a single finding may lead to misdiagnosis. Rather, a comprehensive approach using multiple elements of the history, physical examination, and laboratory data should be used to risk-stratify patients to make informed decisions regarding imaging, treatment, and disposition. This approach should focus on the history and physical examination findings that have the greatest predictive values.

**History**

The history and review of systems provide insight into the patient’s symptoms and help determine alternative diagnoses. A prior history of similar symptoms suggests an alternative diagnosis, because appendicitis is an acute illness. Furthermore, because the pathophysiology of appendicitis is a progressive process, a patient’s symptoms typically worsen over the course of the illness until perforation of the appendix occurs. At this point, the patient may receive some temporary relief due to a decrease of intraluminal pressure, but will subsequently become very ill from the resultant peritonitis. See Table 83.1 for a list common symptoms and their value in predicting the likelihood of appendicitis. Duration of symptoms is variable and often is not useful in the assessment of appendicitis.

When considering features that exclude appendicitis, findings that decrease the likelihood of appendicitis include absence of RLQ pain and a history of similar pain in the past. Nevertheless, these findings in isolation do not exclude appendicitis as a possible diagnosis and are best used as part of a comprehensive clinical decision making process.

**Physical Examination**

All patients with abdominal pain should be fully disrobed, and female patients should ideally be placed in a room in which a pelvic examination can be performed (see Table 83.1). Classic, eponymous examination maneuvers for appendicitis have overall poor sensitivity but, if present, have a modest predictive value (Table 83.2). Although McBurney’s point tenderness has a low correlation with appendiceal location and is not highly sensitive for appendicitis, tenderness at this location does have a modest predictive value for appendicitis.

A genitourinary examination should be performed to assess for testicular pathology or hernias in males and pelvic pathology in females. Cervical motion tenderness (CMT) is not specific for pelvic pathology and is noted in 28% of female patient with appendicitis. A rectal examination contributes little toward the assessment of appendicitis and is not routinely recommended.6

**DIFFERENTIAL DIAGNOSIS**

There are many diagnoses that mimic appendicitis; alternatively, appendicitis may present atypically and must be considered in all

patients presenting with abdominal pain, not just those with right lower quadrant pain. Table 83.3 lists the most common differential diagnoses for appendicitis.

**DIAGNOSTIC TESTING**

**Laboratory Data**

Laboratory data should not be viewed as diagnostic for appendicitis. Rather, it should be used in association with the patient’s clinical history and physical examination to formulate a more comprehensive assessment of the patient’s condition and further risk-stratify the patient for treatment and disposition purposes.

**White Blood Cell Count**

A patient’s white blood cell (WBC) count does not by itself have the sensitivity, specificity, or predictive value necessary to be clinically useful in diagnosing or excluding appendicitis. An elevated WBC count (>10,000–12,000/mm³) has a sensitivity of 62% to 85%, specificity of 32% to 82%, positive LR of 1.59 to 2.7, and negative LR of 0.25 to 0.46. Even in a subgroup analysis of

Urinalysis

Urinalysis demonstrates pyuria, hematuria, and/or bacteria in up to 48% of patients with appendicitis. These abnormalities are due to the inflamed appendix abutting the ureter, with resultant ureteral inflammation. Nevertheless, findings on urinalysis of more than 30 red blood cells (RBCs)/high-power field or more than 20 WBCs/high-power field are more consistent with urinary tract infections than appendicitis.

Other Laboratory Tests

A serum or urine pregnancy test is recommended for any female of childbearing age with abdominal pain. A basic metabolic panel, liver function tests, and lipase level should be obtained for patients with suspected appendicitis to assess for electrolyte derangements and alternative causes of abdominal pain. Procalcitonin does not currently play a role in the diagnosis of appendicitis due to its poor predictive value. The polymorphonuclear count, in isolation, has no clinical value in the assessment of appendicitis.

Imaging Tests

General Principles

The decision to pursue imaging is based on the provider’s clinical assessment, which combines the patient’s history, examination, and laboratory data to decide on the likelihood of appendicitis. If the likelihood is low (and other significant disease processes have been excluded), the patient may be discharged from the emergency department (ED) or observed with serial examinations in an observation unit (see Chapter e6) or inpatient setting. However, if there is a concern for appendicitis, imaging should be carried out.

Currently, patients rarely undergo surgical removal of the appendix based on clinical features alone. The negative appendectomy rate—the number of normal appendices that are surgically removed—is far lower when imaging is used. Nevertheless, in rare cases of young men with a classic presentation, the decision to perform an appendectomy in the absence of imaging may be pursued at the surgeon’s discretion.

Radiography

Due to their poor sensitivity and specificity, routine radiographs are of no clinical value in the evaluation of appendicitis. The only value of radiographs is to assess for other causes of the patient’s symptoms, such as bowel obstruction or bowel perforation. However, an ileus mimicking bowel obstruction may occur in appendicitis due to peritoneal inflammation, and advanced appendicitis may perforate, resulting in intraperitoneal air on
abdominal radiographs. Therefore, care must be taken to make the final diagnosis based on radiographic findings, although intraperitoneal air often expedites the patient’s disposition to the operating room.

Graded-Compression Ultrasound

Within the medical community, there is a growing awareness of the risks associated with ionizing radiation, and efforts are being made to use methods of diagnosis that reduce or eliminate these risks. Graded compression ultrasound (US) is an imaging tool commonly used in evaluating patients for appendicitis. It is a diagnostic technique in which steady pressure is applied with the US probe to the abdomen to reduce bowel gas and collapse normal bowel to promote visualization of the appendix. Studies involving graded compression US for the diagnosis of appendicitis have reported sensitivities of 75% to 90%, specificities of 83% to 95%, positive LRs of 4.5 to 5.8, and negative LRs of 0.19 to 0.27, with an average positive predictive value of 90%. Table 83.4 lists US criteria for the diagnosis of appendicitis.

The benefits in using US for the diagnosis of appendicitis include decreased cost relative to other imaging modalities, lack of ionizing radiation exposure, and decreased time to diagnosis. Limitations of US use include decreased specificity and increased pain due to the transducer pressure needed for the graded compression process. Most importantly, a number of US examinations cannot visualize the appendix (ie, nondiagnostic) for a number of reasons, including lack of operator experience, patient factors (eg, obesity), superimposed bowel gas, or atypically located appendix. In cases with nondiagnostic US findings, the patient typically requires further imaging with CT (or magnetic resonance imaging [MRI] in pregnancy) or admission for observation and serial examinations. Ultrasound is most useful in children, for whom the risks of ionizing radiation are greatest, and rates of overweight and obese individuals are lower than adults and pregnant females (Figs. 83.3 and 83.4).

A distinction must be made between radiology-based US and bedside (point of care) US examination performed by an emergency clinician. Recent studies have demonstrated that bedside US is not as effective at diagnosing appendicitis, with a sensitivity for diagnosis of 60% to 70%, with specificities of 94% to 98%.

Finally, in women with CMT, masses found on pelvic examination, or concern for a gynecologic cause of the patient’s symptoms, pelvic US is an important study to help determine ovarian pathology or tuboovarian abscesses. This should be performed before CT imaging in an attempt to elucidate an alternative diagnosis and may be completed simultaneously with a graded compression US to assess for appendicitis.

Computed Tomography

CT of the abdomen and pelvis is considered the test of choice for definitive assessment of possible appendicitis in nonpregnant patients. It demonstrates an overall sensitivity of 94% to 100% and specificity of 91% to 99%, with a positive LR of 9.29 to 13.3, negative LR of 0.1 to 0.09, and positive predictive value of 95% to 97%. CT is accurate and consistent in diagnosing appendicitis and decreases the negative appendectomy rate. CT is readily available in most hospitals, can be performed in a rapid fashion, is not operator-dependent, can be interpreted by most radiologists and surgeons, and has a greater likelihood of finding an alternative diagnosis (vs. US; Figs. 83.5 and 83.6).

*It is important to note that the diameter of a normal nondiseased appendix may be up to 11 mm, so the other findings of appendicitis must be factored in when making the diagnosis of appendicitis on CT or MRI. Due to the graded compression technique used in ultrasound, there is more certainty regarding diagnostic criteria for appendiceal diameter.*
To this end, there have been recent studies of low-dose CT protocols for the diagnosis of appendicitis. These low-dose protocols decrease the average dose to approximately 2 mSv, with no detriment in the negative appendectomy rate. However, there is less diagnostic certainty by radiologists about the diagnosis of appendicitis with these studies. These are relatively new protocols that show promise but require more studies before they can be universally adopted.  

Table 83.4 lists CT findings diagnostic of appendicitis. In some cases, the appendix cannot be visualized. In these cases, if CT demonstrates no findings of inflammation in the RLQ, it has been found that appendicitis is unlikely. However, patients with low amounts of intra-abdominal body fat may not display secondary signs of inflammation; consequently, these patients may lack this important marker of appendicitis on CT imaging, leading to false-negative study results. The term *tip appendicitis* refers to obstruction and inflammation limited to the distal tip of the appendix and is a subtle finding on CT that is a common cause of false-negative interpretation.  

To assess for appendicitis, CT should be performed with IV contrast only. Enteric contrast of any type, oral or rectal, contributes little to the assessment of appendicitis. In addition, studies have demonstrated that non–contrast-enhanced CT has acceptable accuracy in diagnosing appendicitis. Furthermore, according to the American College of Radiology’s appropriateness criteria for imaging suspected appendicitis, CT imaging with or without IV contrast are acceptable imaging modalities, with the use of enteric contrast being deferred to institutional preference. Therefore, if there are contraindications to IV contrast, there should be little hesitation to move forward with non–contrast-enhanced CT for the evaluation of appendicitis.  

**Magnetic Resonance Imaging**  
When considering the evaluation for appendicitis, current evidence supports the use of MRI for assessment in pregnant females if US is nondiagnostic. MRI has the advantage of not using ionizing radiation and is not operator-dependent. However, its use is limited by its increased cost, increased time required to acquire images, limited availability, and need for the radiologist or surgeon.
to be skilled in MRI scan interpretation, MRI demonstrates a sensitivity of 85% to 100%, specificity of 95% to 99.2, average positive predictive value of 92.4, and average negative predictive value of 99.7. Table 83.4 lists MRI criteria for the diagnosis of appendicitis.

In pregnant patients, IV gadolinium contrast should not be used when evaluating for appendicitis due to potentially harmful effects on the fetus. Enteric contrast may be used at the discretion of the interpreting radiologist or per institutional protocol.

Combined Imaging Pathways

An imaging pathways that combine US and CT, in which abdominopelvic CT is performed if the graded compression US is nondiagnostic or negative, have demonstrated combined sensitivities of 94% to 99%, specificities of 91% to 97.5%, and significant reductions in CT utilization. It has been projected that this pathway would save $547/patient in imaging costs and $25 million/year in aggregate by reducing imaging costs, unnecessary surgeries, and unnecessary hospitalizations, not to mention decreased radiation exposure. As institutions increase their experience with the use of US to diagnose appendicitis, we think that a combined US-CT pathway will gain acceptance and improve health care delivery.

Interestingly, a so-called radiation-free imaging pathway that combines US and MRI, in which abdominopelvic MRI is performed if the US is nondiagnostic or negative, has been recently studied in the emergency pediatric population, with outcomes similar to those of the combined US-CT pathway. However, at this time, there is a paucity of sufficient data and lack of institutional resources to suggest the routine use of this approach.

Summary of Imaging Methods

Fig. 83.2 illustrates a suggested pathway regarding imaging. For nonpregnant patients, graded compression US may be first considered. In nonpregnant females, a pelvic US may also be considered to assess for pelvic pathology. The ability to visualize the appendix on US is institution-dependent, and the provider’s decision to use US initially may depend on the institution’s level of experience with this modality. If the US studies are negative or nondiagnostic (ie, no appendix is visualized and no alternative pathology is noted), the patient may undergo CT imaging of the abdomen and pelvis with IV contrast (no PO contrast). An alternative to CT imaging in low-risk cases with nondiagnostic US is admission for observation and serial examinations.

If the patient is pregnant, graded compression and pelvic US should always be the initial studies of choice, followed by MRI of the abdomen without IV contrast in cases of nondiagnostic or negative US findings. If MRI is not available, and transfer to a facility with MRI capabilities is not feasible, then, after consultation with a radiologist, general surgeon, and obstetrician, abdominal CT scanning with IV contrast may be considered. However, in low-risk cases, admission for observation and serial examinations is an acceptable alternative.

**Antibiotic Therapy**

Antibiotic therapy should be promptly administered on making the diagnosis of appendicitis or in patients with suspected appendicitis and severe sepsis or septic shock. The choice of antibiotics should include broad-spectrum gram-negative and anaerobic coverage. For nonperforated appendicitis, we recommend ciprofloxacin, 400 mg IV, and metronidazole (Flagyl), 500 mg IV; or ceftriaxone, 1g IV, and metronidazole, 500 mg IV; or ampicillin-sulbactam, 3g IV monotherapy. For perforated appendicitis, we recommend a broader spectrum of antibiotics, such as piperacillin-tazobactam, 3.675 to 4.5g IV, cefepime, 2 g IV, or imipenem-cilastatin, 500 mg IV. Methicillin-resistant *Staphylococcus aureus* (MRSA) coverage is not typically needed to treat appendicitis but may be considered if the patient has previously known MRSA colonization.

**Definitive Treatment**

Definitive treatment of acute appendicitis will depend on whether there are associated complications, and all decisions should be made in consultation with the surgical service. Nonperforated appendicitis with a well-circumscribed abscess should be treated with IV antibiotics and percutaneous drainage. Perforated appendicitis with or without abscess is treated with IV antibiotics and urgent operative intervention.

Nonperforated appendicitis without abscess (ie, uncomplicated appendicitis) is traditionally treated with IV antibiotics and surgical removal of the inflamed appendix. However, recent and historical data have demonstrated that conservative treatment of appendicitis with antibiotic therapy and a period of inpatient observation may be a viable treatment option for certain patients. There is historical precedence for nonoperative management of appendicitis, and recent studies have found that there may be value in risk-stratifying patients with appendicitis based on their CT findings. In appendicitis with low-risk features, antibiotic therapy with a period of inpatient observation is a feasible option.

Features associated with failed conservative management include the presence of a fecalith, abscess, tumor, or fluid collection or appendiceal diameter of more than 1.1 cm. In patients with any of these features, operative intervention is preferred.

A minority of patients treated conservatively may fail the inpatient observation period and still require surgery; a minority of those discharged after conservative treatment carry the risk of recurrence of appendicitis. However, with a negative appendectomy rate of 3.6% to 10% and a complication rate as high as 18%—including small bowel obstruction, adhesions, surgical site infection, and abscess formation—nonoperative care is an option worth considering. The decision regarding definitive treatment of acute appendicitis should be made in consultation with the surgical service and the risks and benefits of conservative treatment versus surgical intervention should be frankly discussed with the patient, surgeon, and emergency clinician.

When the decision is made to proceed with surgical removal of the appendix, in uncomplicated appendicitis, delaying surgery up to 12 hours after diagnosis is made (eg, “waiting until the
based on imaging or, rarely, clinical assessment alone. In this case, antibiotics should be initiated, surgical consultation should be obtained, and the patient should be admitted for operative intervention or, in select cases, IV antibiotics and observation. Based on clinical and laboratory assessment, the risk of appendicitis is low, and no imaging study was performed. In this case, the patient may be discharged home if he or she is reliable, has improved clinical status (ie, feels better), and understands the provider’s thought process and precautionary instructions. Alternatively, if these criteria are not met, the patient may be transferred to an observation unit or hospitalized for serial examinations. If the patient’s imaging results are inconclusive, or if they are negative but the patient is still symptomatic, the patient may be admitted for observation, symptomatic treatment, serial examinations, and kept NPO, although select patients in this category may still be discharged at the provider’s discretion.

**DISPOSITION**

There are three possible disposition pathways when a diagnosis of appendicitis is considered. A diagnosis of appendicitis is made based on imaging or, rarely, clinical assessment alone. In this case, antibiotics should be initiated, surgical consultation should be obtained, and the patient should be admitted for operative intervention or, in select cases, IV antibiotics and observation. Based on clinical and laboratory assessment, the risk of appendicitis is low, and no imaging study was performed. In this case, the patient may be discharged home if he or she is reliable, has improved clinical status (ie, feels better), and understands the provider’s thought process and precautionary instructions. Alternatively, if these criteria are not met, the patient may be transferred to an observation unit or hospitalized for serial examinations. If the patient’s imaging results are inconclusive, or if they are negative but the patient is still symptomatic, the patient may be admitted for observation, symptomatic treatment, serial examinations, and kept NPO, although select patients in this category may still be discharged at the provider’s discretion.

**KEY CONCEPTS**

- Appendicitis is a progressive illness caused by appendiceal luminal distention followed by appendiceal wall ischemia, transmural inflammation, and eventual perforation, with resultant peritonitis.
- Clinical history, physical examination, and laboratory findings need to be combined to formulate a comprehensive assessment. No one finding can definitively diagnose or exclude appendicitis.
- The most useful historical features in evaluating appendicitis are RLQ pain, pain preceding vomiting, and migration of pain to the RLQ.
- The most useful physical findings in evaluating appendicitis are RLQ tenderness and rigidity.
- Cervical motion tenderness is not specific for pelvic pathology and is found in up to 28% of females with appendicitis.
- A rectal examination contributes little and should not be routinely performed in the evaluation of appendicitis.
- The white blood cell count alone is neither sensitive nor specific for appendicitis and offers little in the evaluation of appendicitis.
- When clinicians have a low pretest possibility for appendicitis, the combination of a WBC count below 10,000/mm$^3$ and CRP level below 8 mg/L support the exclusion of appendicitis as a likely diagnosis.
- Nonoperative management of acute appendicitis (IV antibiotics, admission) is gaining support. The patient should not have high-risk features (eg, presence of a fecolith, abscess, tumor, or fluid collection or appendiceal diameter >1.1 cm) and should be made aware of the risk of failed observation as an inpatient or recurrent appendicitis once discharged, both of which would then require surgical removal of the appendix.
- Once the diagnosis of appendicitis is made, in-hospital delay of appendectomy of up to 12 hours has not demonstrated negative outcomes when compared to emergent operative care.

CHAPTER 83: QUESTIONS & ANSWERS

83.1. What percentage of women with acute appendicitis have accompanying cervical motion tenderness (CMT)?

A. 10%
B. 15%
C. 20%
D. 25%
E. 30%

Answer: D. Prior to the advent of routine imaging of the appendix, as many as 25% of women with acute appendicitis were initially misdiagnosed because of the presence of CMT.

83.2. Which of the following statements regarding ultrasonographic visualization of the appendix is true?

A. A compressible appendix is a positive finding.
B. An appendiceal diameter greater than 6 or 7 mm is a positive finding.
C. The sensitivity of ultrasound for appendicitis is 94% to 98%.
D. Ultrasoundography has good reliability for detecting a retrocecal appendix.
E. Ultrasoundography compares favorably with computed tomography (CT) scanning for the detection of appendicitis.

Answer: B. A noncompressible appendix with a diameter greater than 6 or 7 mm in a setting of clinical appendicitis is considered a positive finding. Ultrasound sensitivities are 75% to 90%. It is a less useful modality in the obese, those with peritoneal adhesions, and those with a retrocecal appendix. The sensitivity of helical CT scanning with rectal contrast approaches 98%, much higher than ultrasonography.

83.3. A 27-year-old G3P2 woman at 22 weeks of gestation presents with 2 days of right lower quadrant (RLQ) abdominal pain. It began midline and later became more pronounced in the RLQ. The physical examination was remarkable for RLQ tenderness without rebound. The gynecologic examination was negative except for a nontender gravid uterus, with good fetal movement by transabdominal ultrasound. Urinalysis showed 8 to 10 white blood cells (WBCs)/high-power field (HPF) and occasional bacteria. Complete blood count (CBC) showed a WBC count of 12,700/mm³ with 77% neutrophils. Hemoglobin level was 11 g/dL. RLQ ultrasound was limited, with no visualization of a normal or abnormal appendix, and transvaginal ultrasound did not show an obvious gynecologic or obstetric problem. Repeat examination showed continued RLQ tenderness. What is the most appropriate intervention?

A. Administer cephalaxin for urinary tract infection and schedule a 48-hour clinic recheck
B. Admit for observation and serial examination
C. Obtain surgical consultation for laparotomy  
D. Order a CT scan of the abdomen.  
E. Order a magnetic resonance imaging (MRI) scan  

**Answer:** E. MRI scanning for appendicitis may be helpful in pregnant women, in whom the avoidance of radiation exposure is a significant consideration, and exploratory surgery carries additional risks.

**83.4.** In men and children with classic symptoms and signs of appendicitis, what is the most appropriate initial intervention?  
A. Antibiotics and serial abdominal examinations  
B. CT scan of the abdomen  
C. MRI scan of the abdomen  
D. Surgery  
E. Ultrasonography  

**Answer:** E. In men and children with classic appendicitis, imaging adds little to the evaluation and only exposes patients to unnecessary radiation. However, it has become less and less common for a patient with a history and examination concerning for appendicitis to undergo surgery without further imaging. Ultrasound is the most appropriate initial intervention because it uses no radiation and can often visualize and diagnose appendicitis without significant delay. Graded compression ultrasound for appendicitis is specific but lacks the sensitivity of CT scan so, if the appendix is not visualized, a discussion can be had with the general surgeon to determine if it is necessary to obtain further information (via CT or MRI).
OVERVIEW

Background

Gastroenteritis is an inflammation of the stomach and small and large bowel intestines. Most cases present as a self-limited illness, and most patients have nausea, vomiting, and diarrhea, often with diarrhea being the predominant symptom. Diarrhea is defined as the passage of three or more unformed liquid stools a day, stools of more than 250 g/day, or stool that takes the form of the container into which it is placed. Dysentery refers to an inflammation of the intestine, particularly the colon, causing diarrheas associated with blood and mucus; it is generally associated with fever, abdominal pain, and rectal tenesmus (sense of incomplete defecation).

Gastroenteritis is one of the leading causes of morbidity and mortality worldwide, especially in children. Approximately 180 million cases of acute diarrhea occur each year in the United States, most of which are self-limited and without consequence. The incidence has been increasing due to increased international travel and the increased consumption of raw produce, such as spinach and fresh fruits. Viruses account for most of the infectious causes.

Diarrhea-related deaths in developed countries occur most often in older adults or debilitated patients; Clostridium difficile and noroviruses are most frequently implicated. Patients with C. difficile, HIV infection, or immunocompromised-related enteritis or those with fever and bloody stools require early diagnosis and treatment to maximize good outcomes. Diagnostic testing should be reserved for cases due to specific pathogens that cause a more severe clinical illness or cases due to an outbreak. Clinicians can play an important role in surveillance and mitigating the spread of infection.

Gastroenteritis is classified as being acute or chronic. Acute gastroenteritis is associated with symptoms that last for less than 2 weeks, usually from viral or bacterial causes. Chronic gastroenteritis consists of symptoms lasting for more than 2 weeks that is often caused by parasites or noninfectious conditions.

Pathophysiology

The pathophysiology of an infection related to gastroenteritis involves one of four mechanisms—ingestion of preformed toxins, adherence of the infectious pathogens to the intestinal cell walls, invasion of mucosal cell walls, and production of enterotoxins and cytotoxins. All these mechanisms lead to an increase in fluid secretion and/or a decrease in fluid absorption in the gastrointestinal (GI) tract.

Clinical Features

History

The history should take into account epidemiologic factors that may help identify the likely organism (Table 84.1). For example, travel outside of the United States raises suspicion for traveler’s diarrhea, contact with persons on a cruise ship with a GI outbreak is suspicious for norovirus, a recent camping trip and exposure to river water suggests giardiasis, and recent hospitalization or antibiotic use and patients in long-term care facilities are risk factors for C. difficile infection.

Associated factors are helpful in narrowing the list of possible causative organisms and in initiating treatments. For example, GI symptoms after a short exposure period (1–6 hours) may imply preformed toxins from staphylococcal or Bacillus organisms. Diarrhea lasting more than 2 weeks may indicate the presence of Giardia or other protozoa, although noninfectious causes should be considered, such as inflammatory bowel disease. Norovirus classically causes a sudden onset of severe vomiting and only moderate diarrhea. Large-volume diarrhea usually indicates small bowel involvement, such as viral gastroenteritis or illness due to Vibrio cholerae. Colonic involvement causes smaller volume loss and more likely will be bloody or have fecal leukocytes from invasive organisms. Vomiting without diarrhea generally should not be referred to as gastroenteritis. Other causes should be sought out, such as a small bowel obstruction. A history of fever, abdominal pain, tenesmus, and bloody stools are signs of dysentery and may imply invasive organisms such as Campylobacter or Shigella. Yersinia enterocolitica GI infection often mimics acute appendicitis or regional enterocolitis due to its invasion of the local mesenteric lymph nodes. Patients with lightheadedness and hypotension are likely to be dehydrated from diarrhea and vomiting. Muscle cramping may imply hypokalemia or hyponatremia from lack of oral intake or loss of electrolytes in the diarrhea.

Physical Examination

The physical examination focuses on the patient’s general hydration status and assesses for life-threatening conditions. The emergency clinician should first assess the vital signs. In the clinical setting of gastroenteritis, hypotension and tachycardia likely indicate that the patient is dehydrated. Fever, altered mental status, and a toxic appearance may signify that the patient has severe illness and possibly sepsis. Other disease states may mimic gastroenteritis, and a thorough examination is warranted. For example, a low-grade fever in a patient with tachycardia, tremors, and diarrhea in the presence of a goiter may represent hyperthyroidism.

Evaluation of the skin for the presence of petechiae or purpura, especially in the extremities, can suggest possible sepsis or disseminated intravascular coagulation (DIC). Dry mucous membranes, decreased skin turgor, and decreased urine output may also help gauge dehydration. In infants, an accurate measure of weight loss, lack of tears, decrease in urine output, or depressed fontanelle are all good predictors of dehydration. The abdominal examination focuses on conditions that may mimic gastroenteritis, such as small bowel obstruction, bowel ischemia, appendicitis, and colitis. The examiner should listen carefully for bowel sounds. Generally, bowel sounds are hyperactive in acute gastroenteritis. Abdominal findings such as focal tenderness, rebound, guarding, distention, and rigidity may indicate a surgical abdomen. If the
patient reports blood or mucus in the stool or complains of rectal pain, a rectal examination should be performed to assess for gross blood, mucus, or rectal lesions.

**Differential Diagnosis**

Other diagnoses to consider include small bowel obstruction (SBO), diverticulitis, inflammatory bowel disease (IBD), ischemic bowel disease, appendicitis, malabsorption, celiac disease, and irritable bowel syndrome.

A patient with a history of abdominal surgery who presents with crampy abdominal pain and vomiting, distended tender abdomen, and is not passing any gas or stools is likely to have an SBO. In diverticulitis, pain is generally localized to the left lower abdomen. IBD usually first presents in the young adult as recurrent diarrhea, with cramping. The stool may contain mucus and blood. Risk factors are obesity, smoking, and a family history of IBD, with the highest risk in females and Jewish persons of European ancestry. There may be extraintestinal manifestations, such as uveitis and erythema nodosum. Patients with ischemic bowel may present with abdominal pain, ranging from mild to severe tenderness with peritoneal signs. Risk factors include older age, low-flow states such as dehydration, recent congestive heart failure exacerbation, sepsis, smoking, and atherosclerotic disease and those at risk for thromboembolic events such as atrial fibrillation. Patients with gastroenteritis are generally not critically ill and deterioration is not as rapid as seen in those with ischemic bowel disease.

Viruses account for up to 70% of cases of infectious gastroenteritis, bacteria, 15% to 20%, and parasites, about 10% to 15%. It is difficult to identify the exact organism causing the GI illness on initial presentation. The predominance of vomiting along with upper respiratory symptoms is more likely associated with a viral cause. A rapid onset of vomiting as the predominant symptom may suggest the presence of preformed bacterial toxins. The presence of high fever, fecal blood, abdominal pain, or colitis likely indicates an invasive bacterial organism.

**Diagnostic Testing**

Diagnostic testing for patients with apparent gastroenteritis is guided by the clinical assessment. Routine laboratory tests, including a complete blood count and serum metabolic profile, are not needed in every case. Further evaluation may be required for patients presenting with severe illness or severe dehydration.

Laboratory tests should be done for patients with high fevers, severe abdominal pain, bloody stools or persistent diarrhea. Special attention should be given to older adults with abdominal pain and immunocompromised patients. For most cases of gastroenteritis, if the patient appears well and is likely to have a self-limited illness, stool cultures are not required. Stool cultures should be sent for patients with severe illness, fever of 38.5°C (101°F) or higher, dysentery, persistent diarrhea for 14 days or longer and for patients who are immunocompromised or who have been recently hospitalized or placed on antibiotics. If diarrhea is persistent, stools for ova and parasite should be sent. Stools sent for fecal leukocytes, lactoferrin, or hemoccult testing may help identify colonic inflammation with an invasive organism. Stool studies and culture should be performed when certain bacterial and parasitic infections are suspected, such as *C. difficile*, *Campylobacter*, Shiga toxin–producing *Escherichia coli* (STEC), or giardiasis because targeted antibacterial treatment may be initiated to prevent the spread (eg, in an outbreak of daycare workers) and decrease the duration of symptoms. Tables 84.2, 84.3, and 84.4 summarize specific diagnostic testing for bacterial, viral, and parasitic infections, respectively.

**Management**

Patients who are severely dehydrated should receive an intravenous (IV) fluid bolus of isotonic solution, such as normal saline (NS) or lactated Ringer’s (LR). Electrolytes should be repleted, with special attention to the sodium and potassium levels. Antiemetics prevent ongoing loss of fluids and help with the initiation of oral rehydration therapy (ORT).

The exact cause of vomiting in gastroenteritis is not known, although it is thought to be due to peripheral stimuli arising from the GI tract primarily via the vagus nerve or by serotonin stimulation of the 5-hydroxytryptamine 3 (5-HT₃) receptors in the intestinal tract. These signals are transmitted to the emetic center in the brainstem that stimulates the muscles in the diaphragm, abdominal wall, and intestinal tract to produce vomiting. All the areas involved in the pathogenesis of vomiting are rich in serotonergic, dopaminergic, histaminergic, and muscarinic receptors, thus providing the basis for using serotonin inhibitors, dopaminergic inhibitors, and antihistamines. Odansetron, 4 mg IV, or metoclopramide, 10 mg IV, are safe and cost-effective and can be easily converted to an oral dose. Side effects of odansetron include headache and diarrhea.

The American Academy of Pediatrics (AAP), Centers for Disease Control and Prevention (CDC), European Society for Pediatric Gastroenterology and Nutrition (ESPGHAN), and World Health Organization (WHO) all strongly support the use of oral rehydration therapy (ORT) as first-line treatment for acute gastroenteritis, except in cases of severe dehydration. Although ORT has been extensively studied in children, the results can generally be applied to adults. It is known to be safe and effective as the treatment of choice for mild and moderate dehydration. Morbidity and mortality can be greatly reduced with the use of ORT. It is also associated with fewer major adverse events and results in shorter hospital stays.

Fluids containing glucose and electrolytes provide optimal rehydration due to the cotransport of the water across the intestinal lumen. Some choices of oral rehydration solution (ORS) are the standard WHO ORS (331 mOsm/kg), reduced osmolarity

WHO ORS (245 mOsm/kg), and Pedialyte (oral electrolyte solution for children; 250 mOsm/kg). One systematic review of 15 randomized controlled trials, including 2397 children, has shown that reduced osmolarity rehydration solution is associated with a reduced need for unscheduled IV infusions, lower stool volume, and less vomiting compared with a standard WHO rehydration solution. Simple home remedies such as diluted fruit drinks and chicken broth or commercial solutions such as Gatorade will also suffice.

The official recommendation by ESPGHAN is to hydrate orally with reduced osmolarity or hypotonic fluids. Oral intake of food, if tolerated, should be continued during the illness, because fasting may actually worsen the capacity of the bowel to absorb fluid. The presence of the food in the bowel lumen promotes mucosal recovery and improves fluid absorption.

Antimotility drugs such as loperamide and diphenoxylate hydrochloride can help limit the number of watery stools and prevent dehydration. The initial dose of loperamide is 4 mg orally, followed by 2 mg after each unformed stool, up to a maximum of 16 mg/day for 48 hours. However, in patients with suspected bacterial dysentery, it is recommended that antimotility agents be administered in conjunction with antibiotics because antimotility agents may increase the contact time with the toxins or invasive organisms.

In general, antibiotics are not indicated for the treatment of the vast majority of cases of acute gastroenteritis. However,
### BACTERIAL GASTROENTERITIS

In the United States, foodborne diarrheal illness caused by bacteria has increased over the past decades. The four most commonly reported bacterial pathogens are *Campylobacter*, nontyphoid *Salmonella*, STEC, and *Shigella*. The causes of most diarrheal illnesses are never discovered. Most laboratories are equipped to culture only the common pathogens, and routine stool cultures for diagnostic testing often miss organisms such as enterotoxigenic *E. coli*, enteroaggregative *E. coli*, enteroinvasive *E. coli*, and noncholera *Vibrio* spp.6

There are several risk factors that influence the development of bacterial gastroenteritis. Very young patients have low immunity, and maternal passive immunity is lost after weaning from breast-feeding. Older adults are at risk due to the age-related intestinal mucosal alteration of mucosa production, gut flora, and cell surface receptor affinity for toxins. The use of antacids such as proton pump inhibitors decreases the bactericidal effect of gastric acid. Antibiotic use reduces normal intestinal flora and therefore increases the colonization of pathogens such as *C. difficile*. Immunosuppressed patients such as those with HIV infection or patients on chemotherapy are predisposed to nontyphoid *Salmonella*. Poor sanitation and overcrowded conditions also enhance the spread of infected organisms.

Bacteria organisms are broadly categorized as invasive or non-invasive. Invasive gastroenteritis is a clinical diagnosis made in the presence of signs or symptoms of intestinal mucosal invasion, such as fever, gross or occult blood in the stool, tenesmus (feeling of constantly needing to pass stool), or severe abdominal pain (Table 84.5). Patients with noninvasive gastroenteritis generally do not exhibit fever, produce bloody stools, or experience significant abdominal pain. Noninvasive gastroenteritis likely suggests the presence of a viral pathogen or toxin-producing bacteria. This illness typically is brief and self-limited, and diagnostic testing is not likely to be of benefit (Table 84.6).

### INVASIVE BACTERIA

#### Campylobacter Enteritis

**Epidemiology**

*Campylobacter* is the most commonly diagnosed cause of bacterial enteritis in developed countries. It is more common during the summer months. *Campylobacter* spp. are a common cause of so-called backpacker’s diarrhea, along with *Giardia*, both of which are frequently acquired by drinking water from wilderness sources.

**Pathophysiology**

*Campylobacter* organisms are small, spiral-shaped, gram-negative bacteria. The most common species isolated are *Campylobacter jejuni* (94%), *Campylobacter coli* (1%), and *Campylobacter fetus*. *Campylobacter* spp. produce disease primarily by direct invasion of the colonic epithelium. Most infections are acquired by handling or eating raw or undercooked poultry meat. The primary

*D, Duration; I, incubation; S, source.*
reservoirs for Campylobacter organisms are chickens. Other causes include consumption of tainted beef, pork, raw milk, or untreated water and contact with infected pets (particularly cats and puppies) and farm animals.

Clinical Features
The incubation period for C. enteritis is approximately 2 to 5 days. Disease onset usually is rapid, with signs and symptoms of fever, cramping abdominal pain, and diarrhea. Constitutional symptoms of anorexia, malaise, myalgias, and headache are the rule, and some patients experience backache, arthralgias, and vomiting. Onset of diarrhea often lasts 24 to 48 hours after the onset of fever and abdominal pain. Typically, the stools are loose and bile-colored but then become watery and grossly bloody or melano tic approximately 40% of the time. Gross or occult blood is found in the stool of 60% to 90% of patients with Campylobacter gastroenteritis. At the height of the illness, patients usually pass 8 to 10 stools or more/day.

Most patients recover within a week or less; however, diarrhea can persist for an extended period. Relapses are common, although generally milder than the original episode, and fatalities are rare.

Diagnostic Testing
Because the clinical presentation is similar to that of other invasive bacterial pathogens, the diagnosis of campylobacteriosis cannot be made on the basis of clinical presentation alone. Identification of the pathogen will require stool culture or real-time polymerase chain reaction (PCR) assay; specimens should be obtained from patients with acute enteritis associated with fever, abdominal pain, occult blood, or hematochezia. In borderline cases, stool methylene blue staining for fecal leukocytes is readily available and may help identify patients who are likely to harbor an invasive pathogen. Blood culture results are rarely positive, so these studies are not routinely indicated.

Management
Empirical antibiotic therapy is not recommended for otherwise healthy patients with acute invasive diarrhea, but travel-related diarrhea is an exception (see below). Initial treatment of invasive diarrhea should focus on rehydration; the decision to initiate antibiotic therapy should be deferred pending identification of a specific organism via stool studies. Treatment with antibiotics is not needed for patients who demonstrate clinical improvement by the time results become available.

For patients who are not improving, antibiotic therapy shortens the duration of campylobacteriosis by approximately 1.3 days. Erythromycin, 500 mg bid for 5 days, or azithromycin, 500 mg daily for 3 days, is the recommended first-line therapeutic regimen. Ciprofloxacin, 500 mg bid, can be used and was previously the treatment of choice, but alarming resistance to the fluoroquinolones has emerged, thought to be mainly a result of antibiotic use in the poultry industry. Roughly 20% of Campylobacter strains in the United States are now resistant to fluoroquinolones, and resistance of more than 80% has been documented in Thailand. Campylobacter organisms generally also are resistant to trimethoprim-sulfamethoxazole (TMP-SMX). Relapses can occur, but the likelihood is decreased with antibiotic treatment. Because Campylobacter infection causes an invasive enteritis, antimotility agents are not recommended unless treatment with antibiotics is also given.

Complications of Campylobacter infection are rare. Cholecystitis, pancreatitis, and massive GI bleeding all have been reported, as have meningitis, endocarditis, and osteomyelitis. There is an association between Campylobacter infection and Guillain-Barré syndrome, with an incidence of approximately 1/1000 cases.

Salmonellosis
Epidemiology
Salmonella is the most common cause of bacterial enteritis in the United States. Enteritis caused by this organism affects people of all age groups but particularly children, with those younger than 5 years accounting for 20% of cases. Almost all Salmonella infections are acquired from ingestion of contaminated food or drink. Poultry products and beef are the most common sources; other sources include unpasteurized milk, eggs, fish, and domestic pets. Outbreaks also have been associated with consumption of fruits, vegetables, baked goods, rattlesnake meat, and medicinal preparations. Approximately 10% of household dogs and cats excrete salmonellae, and pet reptiles, such as turtles, snakes, and iguanas, have been responsible for outbreaks.

Cooking contaminated foods decreases the possibility of infection but does not eliminate it. Salmonellae can survive cooking when they are deep inside certain foods and where temperatures may not reach the lethal range. Large outbreaks of Salmonella infection have been traced to contaminated, unbroken, grade A eggs. Although the organism is present in the uncracked egg, thorough cooking usually eradicates or reduces the inoculum to clinically insignificant levels.

Common raw egg–based sources of Salmonella infection include homemade hollandaise sauce, eggnog, Caesar salad dressing, ice cream, mayonnaise, tiramisu, cookie dough (often consumed unbaked), frosting, and French toast mix. Salmonella enterica subsp. enterica serovar enteritidis (ie, S. enteritidis) is the species universally associated with egg-related infections. Patients convalescing from Salmonella-related enterocolitis and those with asymptomatic infection may continue to excrete Salmonella organisms for weeks or months, thus serving as ongoing sources of infection.

Pathophysiology
Approximately 2000 Salmonella serotypes are known to cause human illness. Based on 2010 US surveillance figures, the most common isolates are the S. enterica serovars typhimurium, enteritidis, and Newport, which together account for approximately half of culture-confirmed serotypes. Different Salmonella serotypes show marked variations in invasive potential and are associated with particular presentations: S. enterica serovar typhi with enteric fever (typhoid fever), S. enterica serovar choleraesuis with septicemia, S. enterica serovar typhimurium with acute gastroenteritis, and S. enterica serovar enteritidis infections from eggs.

Relatively large numbers of salmonellae must be ingested for illness to be produced. However, a carrier state can be induced, with ingestion of 10 to 100 times fewer bacteria needed to induce the carrier state relative to the number needed to induce illness. In infants and adults with certain underlying diseases, a much smaller inoculum may produce illness. Decreased gastric acidity or an alteration of intestinal flora resulting from the administration of antibiotics can impressively reduce the size of the required inoculum. Rates of invasive infection and disease severity are increased in infants, older adults, and people with hemoglobinopathies such as sickle cell anemia, malignant neoplasms, or acquired immunodeficiency syndrome (AIDS).

Clinical Features
Family outbreaks and sporadic cases are more common than large epidemics. Ingested salmonellae penetrate the intestinal mucosal
cells and lodge in the lamina propria. After an incubation period of 8 to 48 hours, the typical patient with Salmonella gastroenteritis develops fever, colicky abdominal pain, and loose watery stools, occasionally containing mucus and blood. Nausea and vomiting are common but rarely are severe or protracted. Mild to moderate diffuse abdominal tenderness can be elicited in most patients, but severe tenderness and even rebound tenderness may occasionally be noted. Symptoms usually abate within 2 to 5 days, and recovery typically is uneventful. Sustained or intermittent bacteremia may occur, especially in those with sickle cell anemia, malignancy, or AIDS.

Diagnostic Testing
The diagnosis of salmonellosis is confirmed with stool cultures or a real-time PCR assay. Stool methylene blue staining for fecal leukocytes may help identify patients who are likely to harbor an invasive pathogen. Blood culture results occasionally are positive, and blood samples should be obtained from severely ill or immunocompromised patients. The possibility of an underlying disease or immunodeficiency state should be considered in every patient with a severe Salmonella infection.

Management
Empirical antibiotic therapy is not recommended for otherwise healthy patients with suspected Salmonella enteritis. Antibiotic therapy does not shorten the duration of the disease and may prolong the duration of the carrier state. Although its effectiveness is unproven, antibiotic therapy is recommended for patients with severe colitis and for infants younger than 3 months, adults older than 50 years, and those at risk for severe disease, including those who are immunocompromised, with sickle cell disease, and with prosthetic grafts. Persons who represent a public health risk also should be treated in an attempt to eradicate the carrier state and prevent spread of the organism. Any of these antibiotic regimens is generally effective for the outpatient management of Salmonella gastroenteritis: ciprofloxacin, 500 mg bid for 5 to 7 days; norfloxacin, 400 mg bid for 5 to 7 days; or azithromycin 1 g PO followed by 500 mg/day for the next 6 days. TMP-SMX also can be used if the organism is susceptible. Ciprofloxacin is effective in the treatment of chronic S. typhi carriers; however, treatment with fluoroquinolones can actually prolong shedding of non-S. typhi organisms. Patients requiring hospitalization are best treated with IV ceftriaxone until the results of sensitivity studies become available.

Follow-up with the patient’s primary care physician should be arranged. Food handlers and health care personnel are not allowed to work until their carrier state has been eradicated. Repeated stool studies and further decisions regarding job or school situations will be required. Personal hygiene should be emphasized because untreated patients may continue to shed infective organisms in the stool for weeks or even months. As with other invasive pathogens, the use of antimotility drugs alone is contraindicated. These drugs prolong fever and diarrhea, increase the incidence of bacteremia, and promote development of a carrier state in patients with Salmonella enteritis. However, administration of loperamide is safe when given concomitantly with an antibiotic.

Prevention of salmonellosis depends on cooking meat to an internal temperature of 160°F (71°C) and minimizing how long foods are allowed to remain at room temperature to reduce the chance of bacterial growth to an infectious inoculum. Careful personal hygiene, including handwashing, also is important. Although most patients recover fully without long-term sequelae, up to 30% (primarily adults) will experience transient reactive arthritis. Reiter’s syndrome, consisting of reactive arthritis, conjunctivitis, and urethritis, is a well-known complication and occurs in approximately 2% of patients.

Shigellosis
Epidemiology
Shigellosis, or bacillary dysentery, is worldwide in distribution and is particularly common in countries lacking effective sanitation. Shigella sonnei is responsible for approximately 75% of the infections occurring in the United States. Shigella flexneri causes most of the remaining cases, with Shigella boydii and Shigella dysenteriae responsible for less than 4% of cases.

Shigellosis infections are common in confined populations, such as those in mental or penal institutions, in nursing homes or daycare centers. Children younger than 5 years account for 30% of cases. An increased incidence has been documented among men who have sex with men and in the AIDS population. It is spread by the fecal-oral route, and humans are the only natural hosts. Shigellae can be recovered in cultures of samples taken within 3 hours after contamination. Outbreaks have been associated with recreational water venues such as swimming pools, water parks, fountains, hot tubs, and spas.

Pathophysiology
Unlike Salmonella, which requires a very large inoculum to produce disease, as few as 50 to 100 Shigella bacilli can cause infection. No other enteric pathogen is so efficient at producing overt disease in humans. Infection generally is superficial, localized to the epithelial lining of the colonic mucosa; therefore, bowel perforation or invasion into the bloodstream is extremely rare. Bleeding occurs from superficial ulcerations of the mucosa.

Clinical Features
Clinical presentation varies among Shigella species. S. sonnei typically causes high-volume, watery diarrhea, with relatively few systemic signs. Infection with S. flexneri, S. dysenteriae, or S. boydii typically causes low-volume bloody diarrhea and more severe systemic symptoms.

The usual incubation period is 24 to 48 hours, and clinical manifestations vary considerably, often appearing in a bimodal fashion. Mild watery diarrhea with few if any constitutional symptoms or asymptomatic infection occurs in a small proportion of infected persons. When true dysentery develops, it ordinarily is preceded by a recognizable period of watery diarrhea lasting a few hours to a few days. Patients with dysentery have grossly bloody diarrhea, tenesmus, and constitutional symptoms and signs, such as fever, nausea, vomiting, headache, and myalgias. If symptoms are severe enough, profound dehydration and even circulatory collapse can occur. Children younger than 2 years may have associated neurologic manifestations, usually seizures; lethargy or frank coma develops in a small percentage of patients. S. dysenteriae type 1 infection, rarely diagnosed in developed countries, is associated with the hemolytic uremic syndrome (HUS).

Generally, shigellosis is a self-limited disease. Patients become afebrile in 3 to 4 days, and the abdominal cramping and diarrhea resolve within 1 week. Some untreated patients continue to shed organisms in the stool for 2 weeks or longer, and approximately 10% of patients will have a relapse unless the infection is treated with antibiotics.

Diagnostic Testing
Shigellosis should be considered in every patient with an acute febrile illness associated with diarrhea, especially patients who appear ill or who have dysenteric stools. Fecal white blood cells are present, usually in large numbers, in 85% to 95% of cases,
regardless of the gross appearance of the stool. Occult blood usually is present in the stools of infected patients. Blood leukocyto-
sis is common, and a leftward shift in the differential count is almost always seen. Results of blood cultures for Shigella are rarely positive.

A definitive diagnosis of shigellosis is made with stool culture or real-time PCR assay. Stool culture results are positive in more than 90% of cases when samples are obtained during the first 3 days of illness; however, results are positive in only approximately 75% if samples are obtained more than 1 week after the onset of diarrhea.

Management

Treatment primarily involves the correction of fluid and electrolyte abnormalities. If S. sonnei or S. flexneri is cultured from the stool, the decision to administer antibiotics is based on the patient’s clinical condition and feasibility of sanitary control. Asymptomatic or recovering patients do not need to be treated with antibiotics unless treatment is necessary for public health measures. Patients whose condition is not improving and those who are immunocompromised should be treated with antibiotics.

Antibiotics shorten the clinical course and eradicate the pathogen from the stool, often within 48 hours. Whenever S. dysenteriae is isolated, the patient should be treated to prevent outbreaks of dysentery, even if the patient is asymptomatic when the culture result returns from the laboratory.

In the United States, more than 80% of Shigella organisms are resistant to ampicillin and 47% are resistant to TMP-SMX. Significant resistance has not yet been found to the quinolone agents. Ciprofloxacin, 500 mg PO, and norfloxacin, 400 mg PO bid, are the drugs of choice.

Treatment is required for only 3 days in immunocompetent patients but should be extended to 7 to 10 days in those who are immunocompromised. Antimotility agents may prolong the fever, diarrhea, and excretion of Shigella in the stools and are contraindi-
cated in patients with invasive shigellosis. However, they may be safe when used simultaneously with antibiotics. Follow-up stool cultures should be done for patients treated for S. dysenteriae infection to ensure eradication of the organism. Follow-up cultures, however, are not necessary after treatment for S. sonnei or S. flexneri infection, provided that the patient’s condition improves clinically.

Shigellosis is a nationally notifiable disease. Complications are rare and include bacteremia, Reiter’s syndrome, HUS, toxic megaco-
lon, colonic perforation, seizures, and toxic encephalopathy.

Yersinia enterocolitica Gastroenteritis

Epidemiology

Yersinia enterocolitica, a gram-negative facultatively anaerobic bacterium, is a member of the family Enterobacteriaceae. Y. enterocolitica is a relatively infrequent cause of enteritis in the United States. Yersiniosis is more prevalent in children, and infec-
tions are evenly distributed throughout the calendar year.

Pathophysiology

After oral ingestion, the bacterium invades the intestinal epithe-
lum and localizes to lymphoid tissue of the intestinal mucosa, particularly Peyer’s patches. It then invades the regional me-
senteric lymph nodes. Invasive enteritis is the clinical presentation in approximately two- thirds of patients. Pseudoappendicitis and mesenteric adenitis account for the remainder of presentations. Infection originates from contaminated food or drink. The con-
sumption of contaminated milk or contaminated raw pork has accounted for sporadic cases and several large outbreaks. Fecal-
oral transmission to humans from a variety of animals (particu-
larly dogs, cats, and pigs), and direct person to person spread probably occur, but communicability appears to be low.

Clinical Features

The clinical picture with Y. enterocolitica often resembles that with infection by other invasive intestinal organisms—fever (68%); colicky abdominal pain (65%); watery, greenish, and sometimes bloody (26%) diarrhea; and constitutional symptoms of anorexia, vomiting (39%), and malaise. However, in cases of Y. enterocolitica gastroenteritis, the abdominal pain and diarrhea usually persist for 10 to 14 days or longer.

In a substantial number of patients with yersiniosis, particu-
larly adolescents and young adults, an ileocecitis may develop. In these cases, lower abdominal pain with little or no diarrhea is the predominant symptom, and the clinical presentation may per-
fectly mimic that of acute appendicitis. Postinfection manifesta-
tions, such as erythema nodosum or a persistent polyarthritis, occur in 2% to 5% of patients, mainly adults. Other presentations include sacroilitis, anklyosing spondylitis, Reiter’s syndrome, exudative pharyngitis, pneumonia, empyema, and lung abscess. Y. enterocolitica septicemia is rare but is known to occur, most often in patients with diabetes mellitus, severe anemia, cirrhosis hemo-
chromatosis, or malignancy.

Diagnostic Testing

The diagnosis of yersiniosis can be confirmed with stool cultures or real-time PCR assay; however, most laboratories do not rou-
tinely include Y. enterocolitica in standard stool testing. Yersinia identification can be done by special request if clinically indicated, such as a history of Yersinia exposure, prolonged invasive enteritis despite a negative result on standard stool culture, or right lower quadrant pain with signs of invasive diarrhea. Stool cultures require special techniques and a long time for growth. Patients with Y. enterocolitica often continue to shed organisms in the stools well into convalescence, long after the diarrhea subsides. The mean duration of fecal shedding is approximately 6 weeks.

Management

Generally, Y. enterocolitica infection is self-limited at the diarrheal stage and resolves without treatment. As with other invasive GI pathogens, antiperistaltic drugs are not recommended unless the patient is simultaneously treated with antibiotics.

Treatment with antibiotics is not essential or efficacious in the management of uncomplicated Y. enterocolitica. Yersinia organisms usually are susceptible to TMP-SMX DS, one tablet PO bid, which is the agent of choice when antibiotic therapy is indicated. Doxy-
cycline, 100 mg PO bid, in combination with an aminoglycoside, is an alternative regimen, as is single-agent therapy with a quino-
 lone. In immunocompetent adults, a 3-day course is sufficient; the course is extended to 7 to 10 days if the patient is immunocom-
promised. Treatment should be considered for patients who are still significantly ill at the time stool results return, particularly if they are immunocompromised or have an underlying medical illness, or in cases in which the fecal shedding could represent a public health hazard. In patients who interact with potentially susceptible persons, appropriate steps should be taken to ensure that they do not spread their infection.

Vibrio parahaemolyticus Gastroenteritis

Epidemiology

Vibrio parahaemolyticus is a halophilic (salt-requiring) gram-
negative bacillus found naturally in warm marine environments
such as the coastal seawaters of Japan, the United States, and other temperate zone regions. In Japan, *V. parahaemolyticus* is the most common cause of bacterial enteritis, being responsible for approximately 70% of cases. The typical source is raw fish. In the United States, *V. parahaemolyticus* disease is much less common, although its incidence has been increasing. Cases in the United States are typically related to consumption of raw or undercooked shellfish, especially oysters, although clams, shrimp, lobsters, mussels, cockles, crabs, and scallops all have been implicated. Many cases occur as outbreaks on cruise ships or in persons who have patronized a common restaurant or seafood market. *V. parahaemolyticus* enteritis is much more common in the summer months, with 70% of cases occurring in May to October, when warm seawater temperatures favor replication of the organism. Attack rates from a common source exposure are fairly high, but little evidence is available for human to human spread among family members of infected patients.

**Pathophysiology**

The mechanism whereby *V. parahaemolyticus* causes human enteritis is thought to be related to the production of two thermostable direct hemolysin (TDH) virulence factors. Serotypes that produce one or both virulence factors attach to the colonic epithelium and induce a secretory diarrhea, as well as local cell lysis. An infectious dose of *V. parahaemolyticus* is considered to be 100,000 colony-forming units (CFUs) or more. Although enteritis is the most common clinical presentation, accounting for 60% to 80% of cases, *V. parahaemolyticus* infections also manifest as wound infections (34%) and septicemia (5%). Serious wound infections and septicemia occur primarily in persons with underlying liver disease, alcoholism, or diabetes mellitus.

**Clinical Features**

Signs and symptoms usually appear 8 to 12 hours after the ingestion of contaminated food, but the incubation period can range from 4 to 48 hours. The predominant manifestation is acute diarrhea, but the volume of fluid lost generally is not large. Moderately severe abdominal cramps occur in 88%, nausea in 52%, vomiting in 39%, and fever in 33% of cases. Vomiting generally is not prominent. The illness is almost invariably self-limited and seldom lasts longer than 24 to 48 hours. *V. parahaemolyticus* infection should be suspected when a common source outbreak of acute diarrheal disease occurs in persons exposed to fresh or frozen seafood.

**Diagnostic Testing**

The diagnosis of *Vibrio* gastroenteritis is made by stool culture or real-time PCR assay. Although blood agar and other nonselective media support the growth of this species, isolation from the stool usually requires the use of a selective medium containing thiosulfate, citrate, bile salts, and sucrose (TCBS agar). This selective culture procedure is not part of the standard stool culture in most US hospitals but can be obtained by special request in cases of outbreaks related to consumption of raw or undercooked shellfish, especially in coastal areas.

**Management**

Because the disease is self-limited, most patients require no therapy. Although data on the efficacy of antibiotic therapy are lacking, patients who still have diarrhea when culture results become available may benefit from treatment with tetracycline, fluoroquinolones, ceftriaxone, or another antibiotic, as guided by susceptibility testing. Antimotility agents are not indicated. Because *V. parahaemolyticus* is widely present in coastal waters, the only effective preventive measures are adequate cooking, refrigeration, and hygienic practice in the preparation of seafood for human consumption.

**Enterohemorrhagic (Shiga Toxin–Producing) Escherichia coli**

**Epidemiology**

Enterohemorrhagic *E. coli* was first recognized as a human pathogen in 1982 after two outbreaks of hemorrhagic colitis were traced to undercooked ground beef contaminated with *E. coli* serotype O157:H7 and distributed at a fast food restaurant chain. It is now recognized that *E. coli* O157:H7 is one of more than 30 serotypes of *E. coli* known to produce Shigella-like toxins (STEC) and that these STEC serotypes as a group constitute a major cause of hemorrhagic colitis, HUS, and thrombotic thrombocytopenic purpura (TTP) in humans. Children younger than 10 years are at greatest risk for serious STEC infection. Approximately 15% of children with STEC diarrhea develop HUS.

Inadequately cooked hamburger has caused many large outbreaks. STEC, present in the intestines of healthy cattle, contaminates the meat during slaughter, and the grinding process then transfers the organisms from the surface of the meat to the interior. The infectious dose is low, approximately 100 bacteria. US Department of Agriculture food safety regulations now require that hamburger be cooked to an internal temperature of 70°C (160°F) to kill *E. coli* organisms effectively. Outbreaks also have occurred from consumption of venison, salami, pepperoni, cured mutton sausage, cheese curds, apple cider, raw milk, uncooked cookie dough, fruits and vegetables, from contamination of municipal water supplies, from animal contact in petting zoos, and from person to person spread in daycare centers. Food handlers with STEC-related diarrhea have contaminated meals, causing institutional outbreaks. STEC enteritis is more common in the summer months.

**Pathophysiology**

Ingested STEC multiply in competition with normal bacterial enteric flora, adhere to the intestinal epithelial cells, and elaborate Shiga toxin. Toxins bind to absorptive enterocytes on the luminal surface of the small and large intestines, enter the cell, and irreversibly inhibit protein synthesis, resulting in death of enterocytes. Shiga toxins can then enter the bloodstream via damaged epithelial epithelium and cause the death of vascular endothelial cells by the same mechanism. Endothelial cell lysis is accompanied by platelet activation and aggregation, cytokine secretion, vascular constriction contributing to fibrin deposition, and clot formation within the capillary lumen. Microangiopathy propagates distally as the toxins are carried to the kidneys, causing the clinical syndrome of hematuria and renal failure (HUS). The development of HUS is associated primarily with serotypes that produce Shiga toxin 2. The CDC has estimated that 90% of US cases of HUS are caused by *E. coli* O157:H7.

**Clinical Features**

After an incubation period of 3 to 4 days, patients initially produce watery diarrhea that becomes bloody hours to days later. Approximately 90% of patients report bloody stools. The amount of blood varies, but stools passed may appear to consist wholly of blood, and the infection may masquerade as GI bleeding from noninfectious causes. The bloody diarrhea typically is accompanied by severe abdominal cramps, pain, and often vomiting. Fever is a feature in fewer than one-third of cases and, if present, usually is low grade. Fecal leukocytes are found in approximately 50% of cases, but in small numbers, in contrast with the sheets of white
Blood cells seen in *Shigella* dysentery. Uncomplicated infection resolves spontaneously over 7 to 10 days. A carrier state may last another 1 to 2 weeks, but also resolves spontaneously.

STEC colitis has been associated with two serious complications, HUS and TTP. These clinically similar disorders share the features of microangiopathic hemolytic anemia, thrombocytopenia, fever, neurologic deficits, and renal dysfunction. In TTP, neurologic findings predominate, and renal dysfunction is unusual. The opposite is seen with HUS, which is more common in children, especially those younger than 4 years, occurring in up to 15% of cases. Of these, 5% are fatal. Approximately 22% to 40% of older adults in nursing home outbreaks acquire HUS, and 50% to 80% of these patients die. TTP is seen in 2% to 3% of cases, most often in immunosuppressed patients. HUS and TTP typically appear 5 to 20 days after the onset of infection, and the diarrhea can be totally resolved and forgotten by the time a diagnosis is established. Death from STEC colitis alone or from one of the complications occurs primarily among older adults.

**Diagnostic Testing**

The CDC has recommended that all stools submitted for routine testing from patients with acute community-acquired diarrhea—regardless of age, season, or presence or absence of blood in the stool—be simultaneously cultured for *E. coli* O157:H7 and tested with an assay that detects Shiga toxins to detect non–O157 STEC. Culture-based diagnosis requires specific stool culture techniques. In addition to the routine battery of media, specimens should be plated onto sorbitol MacConkey (SMAC) medium. The O157:H7 strains of *E. coli* are sorbitol-negative at 18 to 24 hours of growth on this medium and can be rapidly identified with various serologic tests, such as latex agglutination or fluorescent antibody testing. A commercial Shiga toxin enzyme immunoassay (EIA) is available to identify non–O157 Shiga toxin–producing strains of *E. coli*.

**Management**

Treatment is symptomatic. Antibiotic treatment is of no clinical benefit and may increase the risk of HUS by eliminating competing bowel flora, so it is not recommended for patients with known infection with *E. coli* O157:H7.

Empirical antibiotic treatment for bloody diarrhea should be approached with caution. It is not recommended in children because of the high risk of HUS. In adults, empirical treatment is recommended only for patients with a temperature over 38.5°C (101°F) because the presence of significant fever suggests a pathogen other than *E. coli* O157:H7.

**NONINVASIVE TOXIN-FORMING BACTERIA**

Pathogens associated with toxin-induced bacterial enteritis are summarized in Table 84.3. In general, gastroenteritis caused by toxin-forming bacteria (classically known as food poisoning) will manifest as an acute noninvasive enteritis, with watery diarrhea, minimal fever, little or no abdominal cramping, and absence of fecal leukocytes and erythrocytes. Treatment is primarily supportive, and diagnostic testing generally is not indicated for otherwise healthy patients. A specific diagnosis may be of help in attempting to identify a common source during large outbreaks.

**Staphylococcus spp.**

**Epidemiology**

*Staphylococcus*–related food poisoning occurs after multiplication of an enterotoxin-forming strain of *Staphylococcus* that is present in the food before ingestion. Food contamination with *Staphylococcus* is extremely common because the organism is ubiquitous in the environment. Most protein-rich foods support the growth of *staphylococci*, especially ham, eggs (even hard boiled), custard-filled pastries, mayonnaise, milk, and salads such as egg, tuna, chicken, potato, and macaroni. Foods that require considerable handling during preparation and are then kept slightly warm after preparation are frequent offenders. Temperatures of 45°F to 140°F (7°C to 60°C) for only a few hours will allow proliferation of the organism in contaminated food and production of sufficient enterotoxin to cause disease. Foods containing sufficient enterotoxin to produce violent illness usually are normal in appearance, odor, and taste. Large outbreaks are common worldwide, particularly in institutions such as school or hospital cafeterias, military bases, airlines, and restaurants.

**Pathophysiology**

Although the bacterium itself is killed by cooking at temperatures above 140°F (60°C), *Staphylococcus* enterotoxin is heat-stable. Thus, once it is present in food, reheating or even boiling will not prevent illness. The toxin has no local effect on the digestive tract. It is a potent stimulator of T lymphocytes in the host, resulting in their proliferation and the release of cytokines. The GI effects are believed to be mediated by the release of interleukin-2, tumor necrosis factor beta, and interferon from mast cells. Stool, vomitus, and blood can be tested for the presence of the enterotoxin, but this is typically done by local health departments or the CDC during large outbreaks and is rarely done in clinical laboratories.

**Clinical Features**

The illness has an explosive onset, beginning 1 to 6 hours after ingestion of the contaminated food. Cramping and abdominal pain, with violent and often-repeated retching and vomiting, are the predominant symptoms. Diarrhea is a variable feature; it usually is mild, occasionally absent entirely, and infrequently profuse. Fever occasionally is present. Staphylococcal food poisoning is short-lived, usually subsiding in 6 to 8 hours and rarely lasting as long as 24 hours. Patients often are recovering by the time they seek medical attention. The short incubation period and multiple cases among persons eating the same meal are highly suggestive of this disease. Examination of the stool is noncontributory, and no practical laboratory test is clinically available to confirm the diagnosis.

**Management**

Rapid, uncomplicated, spontaneous recovery is the rule. Parenteral antiemetic agents help control vomiting. IV fluids should be given to patients who are dehydrated or who have ongoing vomiting, particularly the very young, older adults, and debilitated patients. Antibiotics are of no value because staphylococcal food poisoning is caused by preformed enterotoxins and not by viable microorganisms. Adherence to strict personal hygiene practices by food handlers and immediate refrigeration of foods not intended for immediate consumption are the most important preventive measures. Ordinary refrigerator temperatures prevent production of the enterotoxin. Food should not be allowed to stand at room temperature for long periods before being served.

**Clostridium perfringens**

**Epidemiology**

*C. perfringens* food poisoning is one of the most commonly reported foodborne illnesses in the United States, with at
least 10 to 20 outbreaks reported annually. Most cases occur in large groups, with dozens or even hundreds of persons affected. Illness is caused by the ingestion of meat or poultry heavily contaminated with *C. perfringens* type A heat-resistant spores. The organism also is ubiquitous in the environment and in human and animal feces. Typically, poisoning results from ingesting food that is cooked more than 24 hours before consumption, allowed to cool slowly at room temperature, and then served cool or rewarmed. During this period of incubation, spores that survived cooking germinate, and clostridia multiply to reach sufficient numbers to constitute an infectious inoculum.

**Pathophysiology**

Ingestion of live organisms is required to produce disease, but illness is not caused by infection; rather, it is caused by an enterotoxin produced by sporulation of the organism in the GI tract. The enterotoxin is responsible for all the symptoms of *C. perfringens* food poisoning.

**Clinical Features**

Symptoms usually appear within 6 to 12 hours but can occur up to 24 hours after ingestion of the contaminated food. Frequent passage of watery diarrheal stools and moderately severe abdominal cramping are the major symptoms. Fever, nausea, and vomiting are rare. The illness is self-limited and rarely lasts for more than 24 hours. *C. perfringens* food poisoning should be considered in a patient who experiences an acute onset of abdominal cramps and watery diarrhea shortly after eating a suspect meat or poultry dish and when others who have eaten the same meal are similarly ill. Leukocytes and erythrocytes are not present on stool examination.

**Management**

Occasionally, a patient will need IV fluid replacement. Antibiotics are of no value because of the toxigenic nature and brief duration of the disease. Food poisoning from *C. perfringens* can be prevented by avoiding long periods of warming or cooling of foods that have already been cooked.

**Bacillus cereus**

**Epidemiology**

*Bacillus cereus* is an aerobic, spore-forming, gram-positive rod that is a common cause of foodborne illness. The organism is one of the most frequently isolated soil bacteria. Because of its abundance and the hardness of its spores, *B. cereus* contaminates nearly all agricultural products and plays a major role in the spoilage of food items, including pasteurized milk and milk products. It commonly is isolated from pasta, rice, dairy and dried milk products, spices, dried foods, meat, chicken, vegetables, seafood, fruits, and grains. Because it is ubiquitous and tolerates extremes of temperature, control of this bacterium in the food-processing environment is very difficult to achieve.

*B. cereus* causes two distinct clinical syndromes, an emetic form produced by a heat-stable, *Staphylococcus*-like enterotoxin known as cereulide, and a diarrheal form resulting from a heat-labile enterotoxin known as HBL (a hemolysin consisting of three proteins, B, L₁, and L₂), which is similar to that of *E. coli*. The emetic form usually is caused by the ingestion of contaminated fried rice, although beef, poultry, vanilla sauce, pasteurized cream, milk pudding, pasta, potato, cheese, and infant formula also have been implicated. The diarrheal syndrome usually is associated with ingestion of HBL in meats or vegetables, but reported outbreaks have also involved fish, vegetables, soups, sauces, and dairy products.

**Pathophysiology**

The heat-resistant spores of *B. cereus* survive boiling and then germinate when boiled foods such as fried rice are left unrefrigerated. The vegetative forms multiply and produce toxin. Flash frying or brief rewarming of the food before serving often is not sufficient to destroy the preformed, heat-stable, emetic toxin. Improper holding temperatures for cooked food are the most common feature of *B. cereus* foodborne illness.

**Clinical Features**

The emetic syndrome is clinically indistinguishable from that caused by staphylococcal enterotoxin. After an incubation period of 1 to 5 hours, profound vomiting and abdominal cramping occur in all patients. Diarrhea is present in approximately 25% to 30% of persons affected. The duration is short, usually less than 10 hours, and patients recover uneventfully.

The diarrheal syndrome begins after an incubation period of 6 to 14 hours and is characterized by diarrhea in all patients and by abdominal cramps in approximately 75%. Vomiting occurs in only 20% of cases. The duration of illness ranges from 12 to 36 hours. Symptoms are essentially the same as for food poisoning produced by *C. perfringens*. *B. cereus* food poisoning should be suspected when an illness localized predominantly to the upper GI tract develops less than 6 hours after eating or when a predominantly lower intestinal tract illness occurs 6 to 24 hours after a suspect meal, usually of meats or vegetables.

**Diagnostic Testing**

Because of the brief and noninvasive nature of the illness, diagnostic testing typically is not performed. In response to large outbreaks, public health authorities may elect to test common food sources. Isolation of 105 CFU/g from incriminated foods confirms the diagnosis. *B. cereus* enteric infection can also be confirmed via detection of the emetic or diarrheal toxin in stool, emesis, or foods, but this is done only in reference laboratories and only during investigation of large outbreaks.

**Management**

Both syndromes generally are mild and self-limited. Antibiotics are not indicated because symptoms are mediated by enterotoxins. Parenteral antiemetic agents provide effective relief in patients with violent vomiting. *B. cereus* food poisoning is preventable if boiled rice or cooked foods are promptly eaten or refrigerated and not left to sit at room temperature.

**Cholera and Noncholera Vibrio Species**

**Epidemiology**

In addition to *V. parahaemolyticus*, other halophilic marine *Vibrio* species have increasingly been implicated in acute gastroenteritis associated with seafood. Their epidemiology is similar to that of *V. parahaemolyticus*—presence in coastal seawater, outbreaks associated with eating raw or inadequately cooked shellfish, and an incidence markedly limited to the warmer months of the year. Outbreaks of true cholera continue to occur sporadically along the US Gulf Coast from inadequately cooked crabs or oysters. Other identified foods include imported seafood, cooked rice, frozen or fresh coconut milk, and commercially prepared cut cantaloupe. Cholera outbreaks in the developing world have led to an
increase number of cases of cholera imported into the United States.

Pathophysiology

The difference between cholera and noncholera Vibrio spp. versus V. parahaemolyticus lies in the mechanism of pathogenesis. V. parahaemolyticus produces disease via toxins that cause intestinal mucosal destruction, whereas cholera and noncholera Vibrio strains produce an enterotoxin in vivo that stimulates enterocyte adenylate cyclase, disrupting mucosal fluid absorption and leading to a secretory diarrhea. Therefore, symptoms resemble those of other forms of enterotoxin-induced gastroenteritis and not those caused by invasive pathogens. The enterotoxin of the noncholera Vibrio species is antigenically similar to V. cholerae enterotoxin and produces a similar secretory diarrhea, although it is much less severe.

Clinical Features

Patients with classic epidemic cholera experience copious so-called rice water diarrhea, abdominal cramps, and often nausea and vomiting within 24 to 48 hours after ingesting contaminated seafood. A low-grade fever may be present. In these severe cases (cholera gravis), rates of diarheal fluid loss can reach 1 L/hour; fatality rates can reach 25% to 50% in untreated populations. The median duration of illness is approximately 7 days, unlike the 1- to 2-day course of V. parahaemolyticus infection. Despite the notoriety of the classic form of cholera, the CDC estimates that only 1 in 20 cases is associated with cholera gravis. Most affected patients experience a relatively mild diarrheal illness that may go undocumented.

Another species, Vibrio vulnificus, is also associated with eating raw seafood, especially oysters. V. vulnificus can cause self-limited gastroenteritis, with onset approximately 16 hours after ingestion of contaminated food by healthy persons. In the compromised host, this organism may cause serious wound infections when contaminated seawater comes into contact with open wounds. It may also result in a syndrome of primary septicemia characterized by hemorrhagic bullae of the skin and rapidly progressive septic shock.

V. vulnificus infection is the leading cause of death in the United States associated with the consumption of seafood. Septicemia carries a mortality rate of approximately 50% in patients with significant underlying disease, particularly chronic liver disease. All patients with chronic liver disease, alcoholism, AIDS, or other immunodeficiency states should be advised to avoid all raw shellfish.

Diagnostic Testing

Because these are noninvasive Vibrio species, unlike V. parahaemolyticus, stained fecal smears will not show leukocytes or erythrocytes. Stool cultures will quickly identify V. cholerae if plated on TCBS medium. V. vulnificus infection can be diagnosed with stool, blood, or wound cultures. The clinical laboratory should be notified when this infection is suspected so that specific culture media can be used.

Management

Patients with cholera often will lose enough fluids to require rehydration therapy. The WHO oral rehydration formula has been used successfully to treat cholera worldwide. The use of oral or IV fluid hydration is dictated by the clinical picture. The role of antibiotics in the treatment of intestinal infections caused by noncholera Vibrio spp. has not been clearly established. However, antibiotics will decrease the severity and duration of cholera and may have the same effect on the other diarrheal diseases caused by these marine Vibrio spp.

Antibiotics should be guided by strain-specific sensitivities, if available. Typical choices include a single oral dose of ciprofloxacin, 1 g, azithromycin, 1 g, or doxycycline, 300 mg, or a 3-day regimen of double-strength TMP-SMX bid, tetracycline, 500 mg qid, or erythromycin, 500 mg qid. Preventive measures include use of bottled water, meticulous attention to handwashing before eating and after using the bathroom, avoidance of fecal soiled water sources, thorough cooking of food, peeling of fruits and vegetables, and bathing and toileting at least 30 yards away from drinking water sources. Cholera is a nationally reportable infection.

An oral cholera vaccine is available outside the United States. The oral vaccine appears to provide better immunity, with fewer adverse effects than the previously available parenteral vaccine. The CDC does not recommend this vaccine for travelers, and it is not available in the United States.

If V. vulnificus infection is known or suspected, antibiotics should be initiated immediately because this improves survival. Wounds should be debrided because these will progress rapidly and sometimes mandate fasciotomy or amputation. Single-dose antibiotic regimens include levofloxacin or ciprofloxacin. The combination of doxycycline, 100 mg PO bid or IV, plus a third-generation cephalosporin, such as ceftazidime, 1 to 2 g IV or intramuscularly (IM) tid, is also recommended. Children can be treated with TMP-SMX plus an aminoglycoside.

Enterotoxigenic Escherichia coli

Epidemiology

Enterotoxin-producing E. coli, or enterotoxigenic E. coli (ETEC), is recognized as a major cause of acute diarrheal disease throughout most of the world. It is a major cause of diarrhea in persons traveling to underdeveloped areas, especially South Asia, sub-Saharan Africa, and Latin America. ETEC is increasingly being recognized as a cause of foodborne illness in developed countries, including the United States. Infection is acquired from fecally contaminated food or drink. Unpeeled fruits, leafy vegetables, unsanitary drinking water, and ice are the most common sources. Most tourists are careful about their food and drink, but there seems to be a poor correlation between individual eating habits and the incidence of traveler’s diarrhea. It is likely that the quality of hygiene at a particular food source is the major determinant of risk; travelers should choose locations that have a reputation for excellence in hygiene.

Pathophysiology

For an E. coli strain to cause diarrhea, it must possess a surface factor that allows colonization (although not invasion) of the small intestine and the ability to secrete an enterotoxin that causes the outpouring of fluids and electrolytes into the small bowel lumen. The enterotoxin-induced secretion occurs in the absence of any demonstrable histologic damage to intestinal epithelial cells or to the capillary endothelial cells. E. coli produces heat-labile and heat-stable toxins. The intestinal fluid losses are qualitatively identical to those in cholera and other toxigenic diarrheas.

Clinical Features

After an incubation period of 24 to 72 hours, an abrupt onset of watery diarrhea occurs. Severity varies, with the illness ranging from a fulminant, cholera-like disease to the much more common and milder turista, in which the symptoms of mild, watery
diarrhea and abdominal cramps are more troublesome than life-threatening. Fever is unusual. Vomiting occurs in less than one half of affected adults and is seldom responsible for significant fluid losses. Even in severe cases, the diarrhea seldom lasts longer than 48 to 72 hours, and the response to oral or IV fluids is uniformly good. Milder disease generally subsides more gradually, occasionally persisting for 1 week or longer. Virtually all persons recover completely, without long-term sequelae.

ETEC disease should be suspected when a child or adult has frequent watery diarrhea and few other symptoms. It often is passed off as mild nonspecific gastroenteritis and resolves spontaneously. ETEC is the most common cause of traveler’s diarrhea, so most people who acquire toxigenic diarrhea while visiting a developing nation probably have this disease.

**Diagnostic Testing**

There is no easy rapid means for the laboratory diagnosis of ETEC infection. Methods that rely on identification of specific *E. coli* serotypes are unreliable because *E. coli* is part of the normal colonic flora, and its ability to produce enterotoxin is not restricted to any specific serotype. Methods based on detection of the heat-stable and heat-labile toxins through the use of the real-time PCR assay have been developed but are generally available only in reference laboratories. Stool preparations show no erythrocytes or leukocytes.

**Management**

Because ETEC infection is almost always a self-limited disease, no treatment other than maintaining hydration is required. However, if the organism is identified while symptoms are still active, or if the patient is traveling in an endemic area, antibiotics can afford clinical relief. For milder symptoms, a single oral dose of ciprofloxacin, 750 mg PO bid, in addition to loperamide is effective. For more severe symptoms, TMP-SMX, 160 mg/800 mg, or standard doses of a fluoroquinolone for 3 days should eradicate the organism.

**Clostridium difficile** *Colitis*

**Epidemiology**

*Clostridium difficile* (*C. difficile*) is an anaerobic, spore-forming, gram-positive bacillus that is one of the leading causes of health care–associated infectious diarrhea. It has been associated with a range of illnesses, from asymptomatic colonization to severe diarrhea, pseudomembranous colitis, toxic megacolon, intestinal perforation, and death. It is the leading cause of morbidity and mortality among hospitalized older adults. In 2001 to 2010, there were an estimated 2,773,521 discharges with a diagnosis of *C. difficile* colitis identified in the United States based on inpatient registries. Compared with the 2001 to 2005 period, the 2006 to 2010 period witnessed a 47% increase in the rate of *C. difficile* colitis. The increased rates may be due to the increased incidence of *C. difficile* colitis and possibly the emergence of a highly virulent strain of *C. difficile*. The alarming increase in *C. difficile* cases underscores the need for contact isolation procedures when there is a suspected case in the emergency department (ED).

**Pathophysiology**

*C. difficile* infections are usually related to antibiotic use that alters the gut flora and allows the *C. difficile* bacteria to colonize and proliferate. *C. difficile* colitis can manifest concomitantly with current antibiotic use and up to 3 to 4 weeks afterward, although most *C. difficile* infections will occur within 2 weeks of using an antibiotic. Other risk factors include recent hospitalization, living in a long-term care facility, and use of antacids. *C. difficile* spores are highly resistant to heat, acid, and antibiotics, making them highly contagious for person to person or surface to person infections. *C. difficile* bacteria secrete toxins A and B that cause inflammation, mucosal injury, and secretory diarrhea. Infections may lead to a pseudomembranous colitis, toxic megacolon, or even colonic perforation.

**Clinical Features**

Manifestations of *C. difficile* colitis include watery diarrhea up to 10 to 15 times daily, with lower abdominal pain, cramping, low-grade fever, and leukocytosis. Fever is associated with *C. difficile* colitis in about 15% of cases. The physical examination initially focuses on the patient’s fluid status. The emergency clinician should assess for dry mucosa, tachycardia, hypotension, and light-headedness. The abdomen is assessed for evidence of an acute surgical process. A rigid or distended abdomen may represent bowel perforation. A stool sample should be taken for culture and hemoccult testing. The examiner should wear gloves and a protective gown. Vigorous handwashing with soap and hot water after each patient encounter should be performed to decrease person to person infections because hand sanitizers do not kill *C. difficile* sufficiently.

**Diagnostic Testing**

The stool of infected persons should be assayed for *C. difficile* toxins A and B. Nucleic acid amplification tests (NAATs) for *C. difficile* toxin genes, eg, PCR assays, are superior to EIA for toxins A and B and are therefore the recommended diagnostic test. Glutamate dehydrogenase (GDH) screening with subsequent toxin A and B EIA testing has a lower sensitivity but is an alternative diagnostic approach when NAAT testing is not available. In addition, a complete blood count (CBC), metabolic panel, and lactate level determination should be considered based on the patient’s fluid status and severity of symptoms. Leukocytosis in the setting of *C. difficile* colitis is common and the WBC count is often greater than 15,000 cells/mm³.

Persons at extremes of age tend to have more severe infections. The past decade has seen the emergence of a fulminating form in patients older than 65 years. Older adults with a leukocyte count greater than 20 × 10⁹/L, nosocomial infection, renal failure, and immunosuppression are at increased risk for complications such as toxic megacolon, shock, need for colectomy, and death. If a person has any of these risk factors, appears septic, and has a tender distended abdomen, an emergent colonoscopy is recommended to evaluate for toxic megacolon or the presence of pseudomembranous colitis.

**Management**

The management of *C. difficile* colitis includes discontinuation of any inciting antibiotic and rapid initiation of treatment. Metronidazole, 500 mg PO tid for 10 to 14 days, is the first drug of choice for mild to moderate *C. difficile* colitis. Vancomycin, 125 mg PO qid for 10 to 14 days, should be used for severe *C. difficile* colitis. Patients generally become afebrile and show clinical improvement within 36 to 72 hours.

The diarrhea usually resolves over 5 to 7 days, even though results of toxin assays and stool cultures may remain positive for weeks. Up to 50% of patients experience a relapse regardless of the antibiotic chosen, its dosage, or duration of treatment. Risk factors for recurrent disease include new exposure to antibiotics, age older than 65 years, severe underlying disease, low serum albumin level, need for admission to an intensive care unit, and...
Viral gastroenteritis

Most cases of gastroenteritis have viral causes, which include norovirus, Sapovirus, rotavirus, adenovirus, and astrovirus. Clinical features suggestive of a viral cause consist of an intermediate incubation period (24–60 hours) and short infectious duration (12 to 60 hours). Since rotavirus vaccine has been increasingly used in children, the rate of rotavirus-associated gastroenteritis has significantly decreased.

Patients with a viral gastroenteritis can present with nausea, vomiting, abdominal cramping, and diarrhea. Physical findings may include fever and abdominal tenderness. Patients with a more severe illness can present with symptoms and signs of dehydration. Norovirus and rotavirus are among the two most prevalent viral causes of gastroenteritis. Table 84.7 and Table 84.3 contain summaries of common causes, clinical features, diagnostic studies, and treatment of viral gastroenteritis.

Norovirus

Epidemiology

The norovirus, previously referred to as the Norwalk-like virus, is the most common cause of acute gastroenteritis in children and adults and usually occurs in the winter months. It is also the most common cause of foodborne disease and person to person outbreaks in the United States. Norovirus causes approximately 20 million illnesses/year, with approximately 400,000 ED visits. Patients who are immunocompromised and at extremes of age (adults > 65 years and children < 5 years) are at greatest risk of complications and death.

Pathophysiology

Transmission of norovirus occurs via the fecal-oral route (eg, ingestion of contaminated food and water and exposure to airborne droplets of vomitus-containing viral particles and fomites. It has an incubation period of 1 to 2 days, with symptoms typically lasting for 48 to 72 hours. Norovirus is highly infectious for all age groups, and a small amount of inoculum (≈100 virions) is needed for virus transmission. Shedding of the virus in the stool can occur up to 2 to 3 weeks after onset of symptoms.

Clinical Features

The onset of symptoms is commonly abrupt and associated with a rapid recovery. Vomiting is a prominent feature. Patients develop diarrhea that is usually moderate in amount, defined as four to eight stools over a 24-hour period. The diarrhea is characterized as nonbloody stool with a loose to watery consistency that lacks mucus. Associated symptoms include generalized malaise, myalgias, headache, and fever, which occur in approximately 50% of cases. Infection may be protracted and symptoms may be present for a longer period due to prolonged viral shedding, especially in the immunocompromised patient. Postinfectious complications of the condition include dyspepsia, reflux, and constipation. In rare circumstances, patients may present with central nervous system (CNS) complications, such as seizures and encephalopathy.

Diagnostic Testing

The diagnosis of viral gastroenteritis is commonly based on clinical features of the condition. A norovirus outbreak in the community is suspected when these criteria are met: mean incubation period of 24 to 48 hours; mean duration of illness of 12 to 60 hours; presence of vomiting in more than 50% of cases, and absence of bacterial pathogens on stool cultures. These criteria have a 99% specificity and 68% sensitivity for the diagnosis. Identification of the exact causative viral agent is not necessary in most cases. However, in the setting of an outbreak, it is very important to isolate the causative organism so that successful mechanisms that disrupt viral transmission can be recognized. The main laboratory tools to diagnose norovirus infection are genomic amplification via the reverse transcriptase polymerase chain reaction (RT-PCR), immunoassays, and electron microscopy. RT-PCR can detect a stool viral load as low as less than 100 particles/g. PCR testing can also be performed on food and environmental samples. In comparison to RT-PCR, immunoassays have a lower sensitivity and specificity and hence have limited use in the diagnosis of sporadic cases of gastroenteritis. Electron microscopy is best used for the diagnosis of viral gastroenteritis due to rotavirus and astrovirus because large viral loads are shed in these conditions.

Management

Viral gastroenteritis due to norovirus has no specific treatment. Management is based on the clinical condition of the patient. Supportive care, including oral hydration or IV fluid replacement, may be required. Implementation of proper hand hygiene is key to prevent the disease from occurring. During norovirus gastroenteritis outbreaks, patients should be placed on contact precautions in a cohort setting. Routine disinfection and cleaning of environmental surfaces and equipment should also take place.15

Rotavirus

Epidemiology

The name rotavirus originated from the Latin word rota, meaning wheel, based on the classic appearance of the virus under electron microscopy. The virus predominantly infects infants and young children, with a milder disease occurring in adults. Prior to the development of the rotavirus vaccine, rotavirus was the leading cause of diarrhea in the United States among infants and children. Rotavirus is a stable virus and primarily transmitted via the fecal-oral route and direct contact with contaminated surfaces. In the United States, epidemics occur typically in the winter and spring, from December to June.

Pathophysiology

Pathogenesis of the illness is associated with diarrhea, which occurs as a result of three main mechanisms—the direct effect of the rotavirus enterotoxin NSP4, loss of brush border enzymes, and activation of the enteric nervous system.

Clinical Features

Clinical features of rotavirus infection in children include fever, nausea, vomiting and nonbloody watery diarrhea. The virus has an incubation period of approximately 2 days. Symptoms can last from 3 to 8 days. Patients may also present with loss of appetite and signs of dehydration, including dry mucous membranes and decreased urinary output. Children with rotavirus can also have concurrent respiratory symptoms; 2% to 3% have CNS complications, including seizures, encephalopathy, and encephalitis. A milder form of rotavirus infection occurs in adults, especially in household members of infected children. Older adults and immunocompromised patients are at increased risk for more severe disease with protracted illness. This is important to help determine the duration of isolation and repeat testing to ensure eradication of the virus. Rotavirus has been anecdotally implicated in cases of necrotizing enterocolitis, intussusception, and biliary atresia.16

Diagnostic Testing

Rotavirus infection is diagnosed using antigen detection in stool samples. Large viral loads are shed, making electron microscopy a useful diagnostic test. Additional methods include immunoassays such as the enzyme-linked immunosorbent assay (ELISA) and latex agglutination. ELISA will detect virus from the onset of clinical symptoms. Nucleic acid testing, such as via the PCR assay, is the most sensitive test.17

Management

Rotavirus is a self-limited illness that lasts for a few days in healthy individuals. Treatment involves supportive care and managing fluid status. Hospitalization is required in approximately 1 of 70 children infected with the virus.

Prevention of rotavirus infection occurs with the use of two, live, attenuated oral vaccines—the pentavalent human bovine rotavirus reassortant vaccine (RV5, PRV, RotaTeq) and attenuated human rotavirus vaccine (RV1, HRV, Rotarix). The two vaccines have similar efficacy and safety profiles. Studies have shown that the vaccines are very effective in preventing the viral illness and hospitalization due to rotavirus gastroenteritis.

The CDC recommends the following vaccination schedule: RotaTeq (RV5), to be given in three doses at ages 2, 4, and 6 months and Rotarix (RV1), to be given in two doses at ages 2 and 4 months. Rotavirus vaccines are contraindicated in certain infants. Children who have a latex allergy should not receive the RV1 vaccine because the applicator contains latex. Additional rotavirus vaccine contraindications include an allergy to any of the ingredients in the vaccines, anaphylaxis to a previous vaccine dose, history of intussusception, and severe combined immuno-deficiency (SCID).18 Neither natural infection nor vaccine ensures protection from future infections, so vaccinated and unvaccinated children may develop multiple episodes of rotavirus gastroenteritis. The rotavirus vaccinations have been estimated to reduce rotavirus gastroenteritis by more than 90% among infants in all care settings and more than 70% for children aged 1 to 4 years.19

Parasites

Table 84.8 lists the clinical features of common parasites causing gastroenteritis; Table 84.4 summarizes appropriate diagnostic tests and treatment.

Giardia

Epidemiology

Giardia lamblia is a well-known protozoan parasite that causes sporadic or epidemic gastroenteritis worldwide. The illness occurs more commonly in developing countries that have poor sanitary conditions. Approximately 20,000 cases occur in the United States on an annual basis, with the peak being in the summer to fall months. Infants, young children, travelers, immunocompromised individuals, and patients with cystic fibrosis or hypochlorhydria are at greatest risk for developing the disease.

Pathophysiology

G. lamblia exists in two forms, trophozoite (active form) and cyst (inactive form). Trophozoites attach to the mucosal lining of the small intestine and cause symptoms. This active form of the parasite is unable to survive outside the body for an extended period of time and hence cannot spread infection to others. The cystic form, however, is viable outside of the body for prolonged periods and, once ingested, changes into the trophozoite form. Trophozoites generate the cysts that exit the body via the feces.

Giardia infection is transmitted via cysts through several routes, including ingestion of contaminated food and water and fecal-oral route transmission. Infection can result from the ingestion of as few as 10 cysts. Giardiasis is a common cause of diarrhea that occurs in hikers exposed to contaminated water. Person to person transmission can also occur in settings with poor hygiene—for example, child care settings with children who are not toilet-trained. Infection can also be transmitted via anal intercourse.

Clinical Features

Clinical features of acute giardiasis consist of sudden onset of diarrhea associated with malaise, weight loss, nausea, abdominal cramping, and bloating. Stools are characterized as being foul-smelling and fatty.

Diagnostic Testing

Immunofluorescent assays, immunochromatographic assays, and molecular tests are available. Molecular tests can identify ova and parasites, especially in the acute phase, when cysts and trophozoites appear in the stool. In subacute, chronic, and asymptomatic cases, trophozoites may be present in the stool in small numbers or on an intermittent basis. Collection of multiple stool samples (eg, three stool samples collected on separate days) can increase sensitivity of the test.

Biopsy of duodenal-jejunal tissue or aspiration of the duodenaljejunal area by endoscopy may be required to make the diagnosis when repeated stool samples tested for ova and parasites do not yield any organisms.

Management

Treatment of symptomatic cases consists of metronidazole, 500 mg PO bid, or 250 mg PO tid daily for 5 to 7 days. A single PO dose of tinidazole, 2 g, or nitazoxanide, 500 mg PO bid for 3 days, can also be given. Alternative agents include albendazole, mebendazole, and quinacrine.

Treatment of asymptomatic giardiasis is controversial. An asymptomatic carrier can be someone who was initially diagnosed and treated for giardiasis and who now has no clinical symptoms but still has a positive stool culture. Asymptomatic carriers, especially children and food handlers, may need to be treated to reduce the risk of spread and decrease the risk of developing chronic intermittent diarrhea. In endemic areas, the reinfection rate is high; therefore, treatment may not be cost-effective.

Prevention of the disease is promoted by the use of strict handwashing and the avoidance of ingesting contaminated water. To avoid spread of illness in hospitals, patients diagnosed with giardiasis and who are incontinent or wearing diapers should be placed on contact precautions.

Amebiasis

Epidemiology

Amebiasis is caused by the protozoan Entamoeba histolytica, which is found worldwide. The genus Entamoeba is comprised of many species, but E. histolytica is the only one linked to disease pathology.

Amebiasis is more common in developing countries with poor sanitary conditions. Most E. histolytica infections are asymptomatic, with only 10% of carriers presenting with symptoms. Approximately 50 million cases of invasive E. histolytica disease occur worldwide each year. Specific groups of individuals are more predisposed to amebic colitis, such as those at the extremes of age, pregnant females, and maldnourished individuals. Travelers to endemic areas are also at risk for infection.

Pathophysiology

E. histolytica exists in two forms, the trophozoite and cystic forms. The parasite is transmitted by the ingestion of the cystic form, which is the infective stage of the disease. Cysts can survive in the environment for weeks to months and can be found on the contaminated hands of food handlers or in fecally contaminated food and water. The infection can also spread through ingestion of cysts via anal-oral sexual practices. Trophozoites are formed when excystation occurs in the terminal ileum or colon, resulting in the invasive stage of the disease. Trophozoites can cause tissue destruction by penetrating into the colonic mucosal barrier, leading to secretory bloody diarrhea and colitis. Extraintestinal disease can also occur by the hematogenous spread of trophozoites via the portal circulation to the liver and other organs.

Clinical Features

Acute amebic dysentery has an incubation period that ranges from 1 week to 1 year. Patients present with acute onset of severe abdominal cramps associated with fever, profuse, bloody diarrhea, and tenesmus. Gradual onset of symptoms can result in chronic amebic colitis. Individuals present with intermittent diarrhea, with two to four foul-smelling stools daily, usually containing blood-streaked mucus. Associated symptoms of fever, weight loss, abdominal cramping, and flatulence can be present. The clinical condition may have alternating symptomatic and asymptomatic periods, which last over months to years. The most common serious complication of amebic colitis is amebic liver abscess.

Diagnostic Testing

Diagnosis of amebic colitis in the past was based on microscopic identification of cysts and trophozoites in stool samples. Trophozoites can also be identified in biopsy samples that can be obtained during colonoscopy. The development of stool antigen assays has enhanced the diagnostic process for amebic colitis. EIA kits for E. histolytica antibody and antigen detection are available. Molecular
FOOD POISONING

Principles

Foodborne gastroenteritis is an illness caused by the ingestion of food contaminated by viruses, bacteria, or bacterial toxins. Food poisoning is the term typically used for gastroenteritis caused by the ingestion of preformed toxins, such as staphylococcal toxins, B. cereus toxins, histamine-like substances from scombroid fish poisoning, ciguatoxins from ciguatera fish poisoning, or Clostridium botulinum toxins.

The enterotoxins can also be produced in vivo after the ingestion of the bacterium and subsequent production of the enterotoxin in the intestinal lumen. Examples are C. perfringens, B. cereus, C. botulinum, enterotoxigenic E. coli, Vibrio cholerae, non-cholera Vibrio spp., such as V. enterocollitica, and Shiga toxin-producing E. coli. See the earlier section (“Noninvasive Toxin-Forming Bacteria”) for detailed background, clinical presentations, diagnosis, and treatment for each of these organisms. Scombroid and ciguatera fish poisoning are discussed in this section.

Clinical Features

Food poisoning usually manifests 1 to 6 hours after the ingestion of preformed toxins from Staphylococcus, B. cereus (short incubation form), and scombroid fish or ciguatera fish poisoning. Moderate incubation periods of 8 to 16 hours are seen after the ingestion of toxin-forming bacteria such as C. perfringens or B. cereus (long incubation form). Longer incubation periods of more than 16 hours are associated with ETEC, STEC, and Shigella and Vibrio spp.

The clinical presentation usually involves an abrupt onset of nausea, vomiting, and abdominal cramping followed by watery diarrhea. Fever is usually absent, and symptoms should resolve within 24 hours. In some cases, B. cereus predominantly causes diarrhea and cramping. Often, there is a clear food exposure, such as at a picnic with many people in attendance who have the same illness at the same time.

Diagnostic Testing

Diagnostic testing is usually not indicated in cases of food poisoning, and most individuals will recover within 24 hours. A detailed history of the timing, types, and places of recent sources of food ingestion should be obtained. Similar patterns of GI illness involving others who may have ingested the same foods will probably identify the causes. If identification for outbreak surveillance is needed, stool samples can be sent to test for specific organisms.

Most state health departments encourage consumers to report food poisoning incidents to their local health department. Physicians and laboratories must report each singular diagnosed infection that is included in a notifiable disease list maintained by local, state, and/or federal agencies (www.cdc.gov/foodsafety). Foodborne illnesses are included in the notifiable disease lists. Examples include: salmonellosis, shigellosis, cholerla, Shiga toxin-producing E. coli (STEC), norovirus, and hepatitis A. Physicians should suspect an outbreak when they are seen by a larger than normal number of people exhibiting the same symptoms.

Management

In general, oral hydration is the mainstay of treatment. Antiemetics such as odansetron, 4 mg PO, or metoclopramide, 10 mg PO, may be prescribed to enhance oral hydration. Antibiotic therapy is rarely required because most patients will have a self-limited illness.

Scombroid Fish Poisoning

Epidemiology

Scombroid fish poisoning remains one of the most common forms of fish poisoning in the United States. The disease takes its name from the family Scombridae (eg, tuna, mackerel, skipjack, bonito, and related species) but results from the ingestion of a wide variety of dark meat fish, including non-scombroid species such as herring, bluefish, anchovy, sardine, amberjack, black marlin, and mahi mahi. The fish species most commonly implicated are mahi mahi, tuna, and bluefish.

Most US cases occur in Hawaii and Florida, followed in frequency by California, New York, Washington, and Connecticut. However, scombroid poisoning can occur in any location where so-called fresh fish are flown in.

Pathophysiology

The meat of implicated species naturally contains unusually high levels of histidine. Scombroid fish poisoning results from the ingestion of heat-stable toxins produced by bacterial action on the histidine present in the dark meat of the fish. The bacteria responsible are normal constituents of the surface marine flora, rather than contaminants. The histidine decarboxylase activity of these organisms produces histamine and histamine-like substances, which cause the symptoms of scombroid fish poisoning. High levels of histamine in the fish correlate directly with the occurrence of the illness.

Formation of the scombrotoxins is directly related to improper preservation and refrigeration of the fish from the time they are caught until when they are cooked. In general, the problem is caused by improper refrigeration by the supplier rather than being the fault of the restaurant serving the fish. Other foods, notably Swiss cheese, contain sufficient amounts of histidine and have also been implicated.

Clinical Features

The symptoms of scombroid fish poisoning resemble those of histamine intoxication. While eating the fish, the patient may note a metallic, bitter, or peppery taste, although many affected fish do not have an abnormal odor or taste. Symptoms usually develop abruptly within 20 to 30 minutes and consist of facial flushing, diarrhea, severe and throbbing headache, palpitations, and abdominal cramps. Other manifestations may include dizziness, dry mouth, nausea and vomiting, and urticaria. The facial flushing resembles a sunburn and can extend over the entire skin surface. The conjunctivae usually are infected. The duration of the major symptom complex generally is less than 6 hours and,
although weakness and fatigue persist longer, the clinical course usually is benign. The attack rate varies very high; most persons sharing the same toxic fish will become ill.

Management

Parenteral antihistamine therapy, such as diphenhydramine, 50 mg IM or IV, or cimetidine, 300 mg IM or IV, usually relieves all symptoms promptly. This is not an allergic reaction, so patients should not be told that they are allergic to these fish, nor should they be prohibited from eating them again in the future. Suspected cases of scombroid should be immediately reported to the health department.

Ciguatera Fish Poisoning

Epidemiology

Ciguatera fish poisoning is a common public health problem, with appreciable economic significance. It is endemic in tropical regions but is found worldwide. Fish caught around Hawaii and Florida cause most US cases but, because the responsible ocean fish are now commonly transported inland, cases can be seen virtually anywhere. More than 400 fish species that frequent coral reefs have been implicated as ciguatoxin carriers, but fewer than 50 are commercially important; these include amberjack, barracuda, grouper, king mackerel, parrotfish, sea bass, snapper, sturgeon, surgeonfish, and ulua.

Pathophysiology

Ciguatera fish poisoning results from the ingestion of the ciguatoxin neurotoxin. Ciguatoxin is produced by the marine dinoflagellate Gambierdiscus toxicus, which attaches itself to marine algae and is passed up the food chain. The lipid-soluble toxin accumulates in the tissues of the larger predacious coral reef fish, with the highest concentrations in the liver, intestines, head, and roe. It does not affect the fish in any way. Only humans suffer its ill effects when the toxin is ingested. Ciguatoxin is heat- and acid-stable, odorless, and tasteless. It is not deactivated by cooking or freezing, nor is the toxin eliminated by drying, salting, smoking, marinating, or pickling. It is not possible to predict whether a fish contains sufficient amounts of the toxin to produce illness.

Ciguatoxin has anticholinesterase and cholinergic properties, but its neurotoxicity is mediated by its effect on sodium channels. Ciguatoxins cause a hyperpolarizing shift of the voltage dependence of channel activation so that sodium channels are open at the resting membrane potential. Spontaneous firing of neurons occurs as tetrodotoxin-sensitive sodium channels are activated, giving rise to the typical neurologic signs and symptoms.

Clinical Features

Ciguatera fish poisoning is usually seen in the spring and summer months. The incubation period is approximately 2 to 6 hours, but a delay of 12 to 24 hours is not unusual. Attack rates are very high—80% to 90% of persons exposed become ill. Symptoms tend to be related to the amount of toxin ingested and vary considerably in their severity. If not fully recovered from an initial ingestion of ciguatoxin, affected persons are likely to have much more serious symptoms from a second ingestion.

Classically, patients exhibit GI and neurologic symptoms. The GI symptoms (eg, nausea, vomiting, profuse watery diarrhea, crampy abdominal pain, diaphoresis) tend to appear first and resolve over the first 24 hours. The constellation of neurologic symptoms consists largely of dysesthesias and paresthesias around the throat and the perioral area—burning feet, which may resemble alcoholic peripheral neuropathy, loose painful teeth, and sometimes CNS changes, such as ataxia, weakness, vertigo, visual hallucinations, and even confusion and coma.

Distortion of temperature perception is vividly described by patients with ciguatera poisoning. Cold allodynia, defined as dysesthesia experienced on contact with cold water or cold objects, is almost pathognomonic of ciguatera poisoning and often incorrectly referred to as cold-hot temperature reversal. Another classic feature is a return or a worsening of all the symptoms after ingestion of alcohol.

Ciguatera poisoning lasts an average of 1 to 2 weeks, but at least 50% of victims are still symptomatic at 8 weeks. The neurologic symptoms, particularly the paresthesias and dysesthesias, tend to persist longer than the GI symptoms and have been reported up to years later.

Management

Treatment is primarily supportive. IV fluids are given to replace volume losses from vomiting and diarrhea, and analgesics are given as needed. In severe cases, the toxin may exhibit some anticholinesterase activity, manifested as bradycardia and hypotension, which can be treated with atropine, 0.5 mg IV, and dopamine, 5 to 20 µg/kg/min via IV drip. Patients should be told to abstain from alcohol in any amount until symptoms have completely resolved.

Pruritus may be managed with a histamine H1 receptor antagonist, such as diphenhydramine 25 mg PO qid, or cetrizine, 10 mg once daily. Amitriptyline, 25 mg bid, can bring about a dramatic reduction in the pruritus and dysesthesias, two of the most disturbing and protracted symptoms.

The naturally occurring compound brevenal was shown to inhibit ciguatoxin-induced neurosecretion in laboratory studies. This compound may prove beneficial in treating the neurologic sequelae of ciguatera fish poisoning.

SPECIFIC GROUPS WITH GASTROENTERITIS

Traveler’s Diarrhea

Epidemiology

Traveler’s diarrhea is the most common illness afflicting people traveling from resource-rich regions to the developing world. Approximately 10 million international travelers develop diarrhea annually, usually within the first week of travel. The traveler’s destination is the most important factor in assessing the risk of developing disease. Ingestion of contaminated food and water is the primary mode of transmission of traveler’s diarrhea.

Pathophysiology

A variety of viruses, bacteria, and parasites cause traveler’s diarrhea. Bacterial and viral pathogens have an incubation period ranging from 6 to 48 hours. Parasitic causes have a longer incubation period, up to 2 weeks in duration. Bacterial pathogens cause approximately 80% of cases. ETEC is the most common bacterial cause for traveler’s diarrhea (see earlier, “Enterotoxigenic Escherichia coli”). Other causative agents are listed in Table 84.9.

Clinical Features

Classically, traveler’s diarrhea presents with passage of three or more unformed stools in a 24-hour period, with at least one of these symptoms: fever, nausea, vomiting, abdominal pain or cramps, or blood in the stools. Patients with a moderately severe

Diagnostic Testing

Diagnostic testing should be reserved for patients with severe or persistent symptoms. Stool cultures are rarely necessary. Cultures are mainly sent to confirm outbreaks. If stool cultures are sent, testing should specifically look for enterotoxigenic *E. coli*, *Shigella*, *Campylobacter*, and norovirus. If the enteritis is chronic (>2 weeks in duration), associated with foul-smelling and excessive flatulence, the stool should be examined for *Giardia*.21

Management

The best strategy regarding traveler’s diarrhea is prevention. Travelers should avoid eating dairy products, raw fruits and vegetables, or undercooked meat and seafood. Peeled fruits are generally safe. Individuals should use water that has been boiled, which is the most reliable method to make the water safe for consumption. Travelers should also avoid ice and food served at room temperature. Table 84.10 lists preventive medications and treatment of traveler’s diarrhea.

The risk of traveler’s diarrhea can be reduced by more than 90% with the use of probiotic antibiotics. However, due to the development of adverse side effects and resistance, prophylaxis is recommended only for individuals with comorbidities that place them at high risk for complications of diarrhea (eg, renal failure patients, patients with inflammatory bowel disease, or patients with ileostomies or colostomies). Prophylactic antibiotics should not be given for more than 2 to 3 weeks.22

The risk of developing traveler’s diarrhea is also reduced by the use of alcohol-based hand sanitizers (containing ≥60% alcohol) and meticulous hand hygiene. The antacid bismuth subsalicylate decreases the incidence of traveler’s diarrhea by 65% due to its antibacterial and antisecretory effects. The recommended dose is two tablets qid or 1 fluid ounce qid. Bismuth subsalicylate should be avoided in those who are allergic to aspirin because it contains salicylate. Potential side effects include blackening of the tongue and stool. It should not be taken for more than 3 weeks.23

Loperamide, an opioid antimotility drug, can decrease the frequency of loose stools. In patients with fever or bloody stools, an antimotility agent should be given in combination with an antibiotic because it may increase the contact time of the toxin or invasive infectious agents with the intestinal mucosa. Children younger than 2 years should not receive loperamide because it is linked with rare reports of paralytic ileus associated with abdominal distention.

The mainstay of treatment for traveler’s diarrhea is hydration. Antibiotics such as quinolones, azithromycin, and rifaximin and antimotility agents can be prescribed, when indicated (see Table 84.8). The decision to initiate treatment for traveler’s diarrhea is based on the initial amount of diarrhea, severity of associated signs and symptoms, and need for resolution of the diarrhea in regard to the patients’ travel plans. Commercially available oral rehydration packets can be used by travelers to maintain their fluid status. In patients with mild symptoms, described as having one to three loose stools/24 hours, with or without mild enteric symptoms, loperamide can be used to decrease the number of loose stools. Bismuth subsalicylate can also be taken to control nausea. Promethazine, an antihistamine, can be given in oral or suppository form for severe nausea and vomiting.

In patients with moderate to severe traveler’s diarrhea, antibiotics can shorten the duration of disease by 1.5 days. The choice of antibiotic is based on the location of the traveler. A fluoroquinolone such as ciprofloxacin is the antibiotic of choice.

*Source: Adapted from references 22 and 23.*
for most geographic locations. It can be given as 750-mg oral single-dose therapy or as a 3-day course. Azithromycin, 500 mg PO daily for 3 days, is the drug of choice to treat Campylobacter, which is a common cause in Southeast Asia. Rifaximin, 200 mg PO tid for 3 days is an alternate antibiotic that can be prescribed for patients with noninvasive illness. It is not effective against invasive pathogens such as Campylobacter, Salmonella, and Shigella spp. for most geographic locations. It can be given as 750-mg oral single-dose therapy or as a 3-day course. Azithromycin, 500 mg PO daily for 3 days, is the drug of choice to treat Campylobacter, which is a common cause in Southeast Asia. Rifaximin, 200 mg PO tid for 3 days is an alternate antibiotic that can be prescribed for patients with noninvasive illness. It is not effective against invasive pathogens such as Campylobacter, Salmonella, and Shigella spp.

Gastroenteritis in the Immunocompromised Host With HIV/AIDS

The evaluation of gastroenteritis in HIV-positive patients deserves special attention because these patients are at risk for opportunistic enteric infections and are more likely to develop chronic gastroenteritis. In addition to the regular enteropathogenic bacterial pathogens, HIV-positive patients, particularly those with a CD4+ count less than 200/mm³, are more susceptible to certain viruses and parasites, such as cytomegalovirus (CMV), Cyclospora, Cryptosporidium, Isospora, Mycobacterium avium-intracellulare complex (MAI), and Giardia. HIV itself may also cause diarrheal illness. Although not precisely clear, it is thought that HIV may cause a direct infection of the enterocytes and invasion of the lymphoid tissues of the GI tract. Patients with an extremely low CD4+ count, less than 100/mm³, typically tend to have opportunistic infections that are chronic in nature.

Clinical Features

The history should ascertain treatment with highly active antiretroviral therapy (HAART), the CD4+ count and viral load. A history of previous enteric pathogen-related diarrheal illness is important because recurrence rates are common. Anal receptive intercourse may predispose the patient to colonic pathogens, such as Giardia, Entamoeba, CMV, Shigella, and Campylobacter.

Antiviral therapy-induced diarrhea has also been known to be the cause of watery diarrhea in HIV-positive patients. In HAART-naive populations, Cryptosporidium and CMV infections are the two most common causes. Chronic high-volume watery diarrhea often is indicative of small bowel disease from one of the coccidia, Cryptosporidium and Cyclospora belli. Although self-limited in the healthy host, coccidial disease often is persistent in patients with CD4+ counts less than 200/mm³. CMV and MAI also produce a chronic illness in those with CD4+ counts less than 100/mm³.

Fever, weight loss, and abdominal pain are prominent; diarrhea is mild to moderate and sometimes bloody, typical of colonic disease. Microsporidia have emerged as a common cause of diarrhea in patients with AIDS in whom the CD4+ count is less than 100/mm³. Salmonella infections, especially with S. typhimurium, are common in immunocompromised hosts. Patients with AIDS who acquire Salmonella enteritis are at increased risk for bacteremia and metastatic focal infection compared with normal hosts. C. difficile enteritis occurs more commonly in patients with AIDS owing to the common use of prophylactic antibiotic therapy and frequent hospitalizations. It is the most common bacterial enteritis in the AIDS population.

Diagnostic Testing

In patients with AIDS, the presenting signs and symptoms generally do not allow consistent classification of diarrheal illness, as is done for the immunocompetent host, because many patients with AIDS have multiple, concomitant enteric pathogens. However, some clinical pictures are typical. Patients with a fulminating clinical course usually have a disseminated infection, such as infection with CMV or MAI complex. Massive weight loss is also associated with diarrhea caused by infection with those two organisms and the coccidia Cryptosporidium and Cyclospora. Voluminous watery diarrhea usually is a result of one of the coccidial organisms, including Cyclospora and Isospora. Patients with a proctocolitis-like picture most often have herpes simplex virus or CMV infection.

Laboratory testing should initially focus on testing stool samples for C. difficile toxins and other bacteria, specifically Salmonella. If the stool is bloody and the CD4+ count is less than 200/mm³, stool should be sent for CMV and MAI testing. If the diarrhea is present for more than 14 days, three stool samples for stool ova and parasites should also be sent. An acid-fast smear should be requested to look for Cryptosporidium, Cyclospora, Isospora, and Cyclospora if suspected as described.

If the patient has suspected infectious colitis but recent stool analyses have been negative for any organism, an inpatient flexible sigmoidoscopy may be performed to enhance the yield of a pathogen. Small bowel biopsy and duodenal aspiration may be indicated when stool examination, cultures, and sigmoidoscopy fail to yield a definitive diagnosis. Small bowel studies are most helpful for detecting infection with Cryptosporidium, CMV, MAI, Giardia, or C. bellii. Small bowel enterocolitis generally presents with watery diarrhea without fever or fecal leukocytes.

Management

Treatment should be directed toward the presumptive causative organism. As for immunocompetent patients, a cautious approach to initiating any antibiotic is suggested. Empirical antibiotic treatment should be started if the patient has fever, bloody stool, appears ill, or has a low CD4+ count. Ciprofloxacin, 500 mg PO, may be empirically initiated while the evaluation is in progress. If Giardia or C. difficile is suspected, metronidazole, 500 mg PO, may be added. If CMV colitis is suspected, foscarnet, 90 mg/kg IV, should be given. See Tables 84.3, 84.4, and 84.5 for treatment of specific organisms.

Treatment failure is common and is often due to incorrect initial therapy. For example, CMV colitis can also mimic invasive bacterial pathogens because it can also cause severe colitis with bloody stool, fever, and abdominal cramps. Treatment failures are also due to the propensity for infections to recur or become chronic. Parasitic infections in immunocompromised patients may be difficult to eradicate, even with correct treatment.

Gastroenteritis in the HIV-positive patient is often complex, prolonged in duration, and difficult to treat. It is recommended that an infectious disease specialist be involved in the care of these patients. Patients who have AIDS or are immunocompromised should generally be admitted for further management.

**KEY CONCEPTS**

- Gastroenteritis is usually self-limited and requires supportive care only.
- Routine laboratory testing or stool cultures are not indicated for most patients.
- Caution should be used in the care of the very old and young. They have the highest morbidity and mortality in gastroenteritis.
- Hand hygiene with soap and water or hand sanitizers will contain the spread of most infectious agents in gastroenteritis.
- Patients with fever, dysentery, bloody stools, severe dehydration, a suspicion for C. difficile, or immunocompromised state should have a complete blood count, electrolytes, and stool cultures sent.
CHAPTER 84 Gastroenteritis

The references for this chapter can be found online by accessing the accompanying Expert Consult website.

- Use of oral rehydration therapy (ORT) for dehydration is a preferred management strategy.
- Hypotonic oral rehydration solution is preferred (e.g., WHO-modified ORT solution).
- The use of antiemetic medications may help with ORT. Odansetron, 4 mg IV or IM, is safe and cost-effective.
- Early realimentation with normal feeding is advised and continuation of breast-feeding is suggested, if possible.
- *Campylobacter* is the most common cause of bacterial enteritis in developed countries.
- The norovirus, previously referred to as the Norwalk-like virus, is the most common cause of acute gastroenteritis in children and adults and usually occurs in the winter months.
- Bacterial pathogens cause approximately 80% of cases of traveler’s diarrhea; enterotoxigenic *Escherichia coli* (ETEC) is the most common cause.
- In patients with fever or bloody stools, an antimotility agent should be given in combination with an antibiotic because it may increase the contact time of the toxin or invasive infectious agents with the intestinal mucosa.
- Classic food poisoning manifests usually 1 to 6 hours after the ingestion of preformed toxins from bacterial organisms such as *Staphylococcus*, *B. cereus*, or *C. perfringens*.
- Food poisoning is generally short-lived (24 hours), and its treatment is generally supportive care only.

- Risk factors for *C. difficile* colitis include recent antibiotic use (1–4 weeks), recent hospitalization, living in a long-term care facility, and use of antacids.
- Evaluation (colonoscopy) for toxic megacolon and pseudomembranous colitis is recommended for patients with *C. difficile* colitis who are older, have a high leukocytosis finding, appear septic, and have a tender distended abdomen. Consider empirical antibiotic treatment for suspected *C. difficile* (metronidazole, 500 mg tid for 10 days) or traveler’s diarrhea (ciprofloxacin, 500 mg twice daily for 1–3 days).
- *Scombroid* poisoning results from eating spoiled dark meat fish; it is not an allergic reaction but results from an ingestion of histamine.
- In addition to the regular enteropathic bacterial pathogens, HIV-positive patients, particularly those with a CD4+ count <200/mm³, are more susceptible to certain viruses and parasites, such as cytomegalovirus, *Cyclospora*, *Cryptosporidium*, *Isospora*, *Mycobacterium avium-intracellulare* complex, and *Giardia*.
- In HIV-positive patients with persistent diarrhea, a small bowel biopsy and duodenal aspiration may be indicated when stool examination, cultures, and sigmoidoscopy fail to yield a definitive diagnosis.
- Consider *Giardia* for diarrhea lasting more than 2 weeks, with foul-smelling stools and symptoms of flatulence, abdominal bloating, cramping, and recent exposure to contaminated river water.

84.1. What is the recommended rehydration therapy for uncomplicated gastroenteritis with moderate dehydration?
A. IV hydration with D, half-normal saline
B. IV hydration with normal saline
C. Oral rehydration therapy with high-osmolarity fluids
D. Oral rehydration therapy with reduced-osmolarity fluids
E. Oral hydration with plain water

Answer: D. WHO recommends oral rehydration therapy with reduced-osmolarity fluids.

84.2. What is the most common documented cause of bacterial enteritis in developed countries?
A. Campylobacter
B. Escherichia coli
C. Giardia
D. Salmonella
E. Shigella

Answer: A. Most infections are acquired by eating raw or undercooked poultry meat. Symptoms of anorexia, malaise, myalgias, and headache are common, as are backaches and vomiting. Diarrhea lags 1 or 2 days after the constitutional symptoms. The syndrome can mimic appendicitis. Antibiotics are rarely needed in healthy patients. Azithromycin is first-line treatment if antibiotics are indicated.

84.3. Of the following choices, which is the correct association?
A. Yersinia—mesenteric adenitis, pseudopappendicitis
B. Shigella—poultry
C. Salmonella—warm marine environment
D. Campylobacter—sickle cell anemia
E. Vibrio—public swimming pools

Answer: A. Yersinia, like Campylobacter, may mimic acute appendicitis. The other correct associations would be Shigella—public swimming pools, Salmonella—sickle cell anemia, Campylobacter—poultry, and Vibrio—warm marine water.

84.4. A 14-year-old boy presents with watery diarrhea that progresses to bloody diarrhea over 4 to 6 hours. He has also had moderate vomiting and significant abdominal cramping, but no other systemic symptoms. He is afebrile with a normal examination, except for diffuse, moderate abdominal tenderness to deep palpation and blood-streaked loose stool on digital rectal examination. Laboratory evaluation shows a mild leukocytosis, and the stool smear shows 12 fecal leukocytes/µL (high-power field). Which of the following is true?
A. Articular and ophthalmologic findings would be typical.
B. Ciprofloxacin is the drug of choice.
C. Endoscopy and biopsy would be the diagnostic tests of choice.
D. He is at risk of late neurologic sequelae.
E. There is likely a recent history of eating undercooked eggs.

Answer: D. This patient is most likely infected with enterohemorraghic (Shiga toxin) Escherichia coli, which often results from eating undercooked hamburger. Watery diarrhea that becomes bloody with significant abdominal pain is typical. The diarrhea may be grossly bloody and mimic inflammatory bowel disease or intestinal ischemia. Stool cultures with specific techniques for E. coli are the test of choice. Toxin assays are also recommended. Endoscopic findings would be identical to those of any other severe colitis. Antibiotics are not effective and may increase the risk of hemolytic uremic syndrome in children. Thrombotic thrombocytopenic purpura (TTP) is a risk in older children and adults.
84.5. A 21-year-old man presents with acute onset of vomiting and retching 2 hours after eating at a restaurant. He also reports two loose stools. He is afebrile, with an unremarkable examination, except for his nausea and retching. What would be the treatment of choice?

A. Antitoxin  
B. Erythromycin  
C. Fluids and antiemetics  
D. Norfloxacin  
E. Trimethoprim-sulfamethoxazole

Answer: C. Staphylococcal food poisoning presents in an acute and classic manner. Symptoms typically last 6 to 8 hours, and patients are often better before they decide to seek care. This is a toxin-mediated syndrome. Offending foods are usually eggs, potato salad, pastries, and mayonnaise. Only symptomatic treatment is necessary.

84.6. A 27-year-old man presents with severe abdominal cramping and diarrhea, with many frequent watery stools. He ate at a restaurant 12 hours before with two friends who have reported the same syndrome. There are no leukocytes or erythrocytes on stool examination. Which of the following statements is correct?

A. Antibiotics may shorten symptom duration.  
B. Fever and vomiting are typical.  
C. Freshly cooked food is the most likely cause.  
D. Ingestion of live organisms is not required for illness.  
E. This syndrome is usually self-limited but can progress to shock and death in rare cases.

Answer: E. Clostridium perfringens is a common source of food-borne illness. Food cooked in advance, cooled, and rewarmed is a typical culprit. This is a toxin-mediated, diarrhea-predominant syndrome that is almost always self-limited. Ingestion of live organisms and/or spores is required, although antibiotics are of no benefit. Symptoms usually appear within 6 to 12 hours, slightly longer than for staphylococcal food poisoning. When huge numbers of organisms are ingested, a hemorrhagic necrotizing enteritis with prostration and shock can occur.

84.7. A 26-year-old woman presents with a complaint of burning pain of her hands and feet. She also reports diffuse aching of her teeth. All symptoms began gradually. They were preceded the day prior by two loose stools, but her review of systems is otherwise negative. She is healthy except for a past history of anxiety, for which she takes prn lorazepam. The physical examination and vital signs are remarkable for mild ataxia. Cutaneous temperature discrimination testing is intact but unpleasant. Which of the following is the intervention of choice?

A. IV thiamine, 100 mg  
B. Magnetic resonance imaging (MRI) scan of the brain and lumbar puncture  
C. Noncontrast CT scan of the brain  
D. Psychiatric consultation  
E. Reassurance and amitriptyline 25 mg at bedtime

Answer: E. Ciguatera fish poisoning is a toxin-mediated process in which gastrointestinal and neurologic symptoms (often bizarre) predominate. Cold allodynia and worsening of the dysesthesia with alcohol are diagnostic. Hyperventilation syndrome, gastro-enteritis, and anxiety can be misdiagnosed.

84.8. A 31-year-old man with known AIDS presents with 2 weeks of profuse watery diarrhea. His only medication is trimethoprim-sulfamethoxazole bid. His last known CD4+ count was 120/mm³. The physical examination was remarkable for oral thrush and mild cachexia. He has continued to tolerate a regular diet, and his level of dehydration is minimal. What is the most appropriate intervention?

A. Acute IV hydration, then discharge on antimotility agents  
B. Admission for serial cultures and possible endoscopy  
C. Combined course of ciprofloxacin and ganciclovir  
D. Initiation of highly active antiviral therapy (HAART)  
E. Lactose-free and low-fat dietary modifications

Answer: B. In cases of AIDS diarrhea, one or more enteric pathogens are found in 80% of cases. Serial stool cultures, blood cultures, and sometimes endoscopy are needed to identify the organisms and develop a treatment plan. HAART is also indicated, but not as a sole intervention. AIDS diarrhea is rarely self-limited with CD4+ counts less than 300/mm³. The most common responsible organisms are *Cryptosporidium*. *E.*

84.9. An 18-month-old child presents with 2 days of copious diarrhea that was preceded by 1 day of vomiting. The past history is otherwise negative except for treatment with amoxicillin for an inner ear infection 4 weeks prior. The child is moderately dehydrated by clinical examination, and there is no abdominal tenderness. The WBC count is normal. What is the most likely diagnosis?

A. Antibiotic-associated diarrhea  
B. *Clostridium difficile* poisoning  
C. Norovirus  
D. Staphylococcal food poisoning

Answer: C. Winter month gastroenteritis in young children is commonly norovirus, especially with the widespread use of the rotavirus vaccine. Vomiting is prominent early but rarely presents after 36 hours. There is rarely abdominal pain, fever, or leukocytosis. The diarrhea lasts 4 to 7 days and is often followed by steatorrhea. *C. difficile* may commonly present 3 or 4 weeks after antibiotic use, but vomiting is rare. Antibiotic-associated diarrhea is mild and usually occurs during the course of antibiotics.

84.10. A 28-year-old man presents with 2 weeks of watery, foul-smelling diarrhea and flatulence. He recently returned from a camping trip in which he participated in water rafting on a river. On examination, he appears nontoxic and afebrile, and the abdominal examination shows only diffuse cramping and bloating. What is the mostly likely causative organism?

A. Enterotoxin-producing *Escherichia coli* (ETEC)  
B. *Giardia*  
C. Rotavirus  
D. *Salmonella*  
E. *Vibrio parahaemolyticus*

Answer: B. *Giardia*. Giardiasis is commonly acquired from the ingestion of contaminated water, typically a camper who has ingested river water. The symptoms include diarrhea, abdominal cramping, and bloating, with foul-smelling stools. The treatment is metronidazole, 500 mg PO bid.
Disorders of the Large Intestine

Michael A. Peterson | Andrea W. Wu

IRRITABLE BOWEL SYNDROME

Principles

Irritable bowel syndrome (IBS) is a chronic, non–life-threatening disorder characterized by abdominal pain and alteration in bowel habits. IBS is an extremely common disorder; estimates put the prevalence in the North American population at 10% to 15%, with women affected twice as often as men. IBS accounts for more than 10% of all visits to primary care physicians and more than 25% of all visits to gastroenterologists. IBS is said to contribute more impairment to quality of life than diabetes or renal failure, although it has no demonstrated long-term mortality consequence.

No specific physical or laboratory abnormalities defining IBS have been identified. It is a functional somatic syndrome that is diagnosed by clinical criteria in the absence of alarm symptoms and findings that suggest other, more urgent diagnoses. Diagnosing IBS is problematic in the emergency department (ED; typically, patients are discharged with a diagnosis of “abdominal pain of unclear cause” or the equivalent.

Although the cause of IBS is unknown, it is associated with several pathophysiologic findings suggesting a disorder of altered gut motility, gut sensation, and perception of intestinal activity. 1 Physiologic testing has since shown that patients with IBS have disturbances in the rhythmical pattern of electrical activity in the intestine and in how the intestine responds to stimulation. Recently, markers of chronic inflammation and altered bowel flora have been found in intestinal tissue of IBS patients, although their significance is not yet known.

Psychiatric conditions often coexist with IBS, ranging from generalized anxiety disorder to major depression. Other associations are fibromyalgia, chronic fatigue syndrome, chronic pelvic pain, and history of previous sexual abuse. 2 In women, symptoms often are related to the menstrual cycle, suggesting a hormonal influence.

Clinical Features

The diagnosis of IBS is defined by clinical criteria in a patient whose symptoms have no other organic explanation. The Rome III criteria (Box 85.1) are often considered as the diagnostic standard, although some practicing gastroenterologists believe these to be inadequate because they do not include one of the most common symptoms, bloating. 3

Patients with IBS experience symptoms intermittently, with the typical patient averaging symptoms on 1 of every 3 days. Complaints include abdominal pain, bloating, and constipation or diarrhea. Pain typically is relieved with defecation; pain that persists suggests another diagnosis. A mucoid discharge from the rectum often accompanies diarrhea. Upper gastrointestinal symptoms such as nausea and dyspepsia can also occur. The physical examination may reveal mild focal abdominal tenderness, which can vary in location, or diffuse tenderness. Constipation (IBS-C), diarrhea (IBS-D), or a mixture of the two (IBS-M) may occur. 2

Pain that is progressive or associated with anorexia or significant abdominal tenderness suggests an alternate diagnosis. Signs and symptoms that point away from the diagnosis of IBS (alarm symptoms) include onset of symptoms after the age of 50 years, unintentional weight loss, anorexia, bloody stools, nocturnal diarrhea, or family history of significant colon disease. 3 In the absence of symptoms suggesting another diagnosis, the clinical criteria have a specificity ranging from 87% to 100%, although the sensitivity may be only 60%. In patients determined to have IBS through correct use of the clinical criteria, follow-up evaluation over many years rarely leads to a change in the diagnosis. 4

A final diagnosis of IBS usually is made in the primary care setting and not in the ED. The ED evaluation seeks to exclude other, more urgent causes for the patient’s symptoms.

Differential Diagnosis

The differential diagnosis of symptomatic IBS depends on the predominant symptoms and includes a host of disorders (Box 85.2). An assessment for pancreatitis, hepatitis, biliary colic, or urologic disorders, including ureolithiasis, may be appropriate, as indicated by the pattern of the presenting complaints.

Diagnostic Testing

No specific testing should be done in the ED on individuals who fit the pattern of IBS.

Management

Not all patients with IBS require treatment; therapy should be initiated only if symptoms diminish the quality of life. Diet, behavioral, and pharmacologic therapies are all used in IBS. The specific therapy will be determined by the type of IBS—IBS-C, IBS-D, or IBS-M. Dietary suggestions include a low-fat diet, reduced nondigestible sugars, and avoidance of gas-forming foods, although none of these has any proven benefit. Although the data are mixed, the most recent evidence has suggested that fiber supplementation may aid IBS-C. 3

Medications with antispasmodic activity (eg, dicyclomine, 20–40 mg four times daily) are used for abdominal cramping, and peripherally acting narcotics, such as loperamide (4 mg orally as an initial dose, followed by 2 mg for subsequent doses), are used to reduce diarrhea. Antibiotics such as rifaximin (550 mg, tid for 14 days) have been shown to reduce symptoms. Osmotic laxatives such as lactulose may be helpful in constipation. Tricyclic antidepressants and selective serotonin reuptake inhibitors have been effective for certain classes of patients with IBS. Evidence has suggested that peppermint oil and probiotics may be of limited use. 4 Nonsteroidal antiinflammatory drugs (NSAIDs) may worsen symptoms.

Disposition

IBS is not a life-threatening disease and can be managed on an outpatient basis as long as other disorders have been excluded.
Diverticulosis denotes the presence of diverticula in the colon. Most patients with this condition are asymptomatic. Diverticulitis denotes inflammation of diverticular tissue, which is usually painful. It is estimated that 10% to 25% of patients with diverticulosis will develop diverticulitis. Complicated diverticulitis is defined by the presence of more extensive disease, including abscess formation, peritonitis, intestinal obstruction, and fistula formation.

The wall of the colon is penetrated at regular intervals by blood vessels, collectively known as the vasa recta, that supply the intestinal layers. The site of vessel penetration is apparently the weakest part of the colon wall because it is at these sites that diverticula form. Although the exact pathogenic mechanism is unknown, one theory is that diverticula form in response to increased intracolonic pressures generated when the colon is processing smaller, non–fiber-containing stools. Recent experimental evidence has suggested that chronic inflammation and an alteration in bowel flora may also play a role.

Patients with diverticular disease exhibit normal resting colonic pressure but higher peak pressure than those without diverticular disease; higher peak pressures lead to herniation of colonic mucosa through the intestinal wall at the vasa recta, creating small, saclike appendages. These appendages (diverticula) typically measure 5 to 10 mm in diameter but, on rare occasions, can grow into huge sacs measuring many centimeters across (giant colonic diverticula). Diverticula are generally asymptomatic. Symptoms develop when inflammation sets in and microperforations of the sac develop, resulting in inflammation of pericolonic structures and abdominal pain.

Classically, it was thought that the diverticular sac was obstructed, leading to stasis and infection, despite the lack of evidence of obstruction in pathologic specimens. Recently, it has been shown that the course of diverticulitis is not influenced by antibiotic therapy but is affected by antiinflammatory agents. Tissue specimens also show markers of chronic inflammation, similar to those found in inflammatory bowel disease.

In uncomplicated diverticulitis, only the pericolonic fat is inflamed. With time, a phlegmon, abscess, or gross perforation may develop. Any extension of disease beyond the pericolonic fat is defined as complicated diverticulitis. The involved colonic segment may fistulize to any adjacent organ, usually the bladder. Adjacent bowel may become obstructed by mass effect from an abscess or may incur an inflammatory ileus. Recurrent episodes can lead to strictures and subsequent colonic obstruction.

Diverticula can also bleed. Severe hemorrhage occurs in 3% to 5% of all patients with diverticulosis and accounts for approximately 40% of all cases of lower gastrointestinal hemorrhage. Bleeding notably occurs in the absence of inflammation and typically is painless. NSAID use is associated with this complication.

**Clinical Features**

**Diverticulosis**

Although approximately 75% remain asymptomatic throughout their lifetime, patients with diverticulosis sometimes have chronic nonspecific abdominal complaints, including bloating, crampy pain, excessive gas, and a change in bowel habits. Diverticulitis will develop in approximately 10% to 30% of patients with diverticulosis.

**Diverticulitis**

Because most diverticula found in persons in the West form in the left colon (in Japan, the right colon predominates), the typical...
presentation of diverticulitis is persistent left lower quadrant pain and tenderness. Pain may begin in the hypogastrium before localizing to the left lower quadrant. Referred pain may occur in the penis, scrotum, or suprapubic region. Right-sided diverticulitis may manifest as right lower quadrant pain and is impossible to distinguish clinically from appendicitis. Additional findings suggest various complications—diffuse tenderness is associated with gross perforation or abscess rupture; dysuria is associated with a colovesical fistula; mass is associated with an abscess; and vomiting or abdominal distention is associated with intestinal obstruction. Fecal matter or gas emanating from the vagina suggests a colovaginal fistula. Almost any adjacent organ can be involved in the inflammatory process. Patients recently diagnosed with diverticulitis who are being treated on an outpatient basis with oral antibiotics and who visit the ED with continuing or worsening symptoms should be evaluated for the possibility of an abscess.

Special care must be taken with older patients or immunocompromised patients because clinical signs and symptoms are much less dramatic, even with more severe disease. Perforation is more common in these patients (up to 40%), manifests with less significant findings, and carries a high mortality rate.6

Differential Diagnosis

A tentative diagnosis of diverticulitis may be based on clinical grounds alone; however, the differential diagnosis should include colonic carcinoma, although it is usually safe to wait until after the acute episode has resolved to investigate this possibility. Additional diagnoses to consider include colitis (inflammatory or ischemic), ureteral stones, inguinal hernia, and pelvic pathology, including ectopic pregnancy or pelvic inflammatory disease, and ovarian pathology, with or without ovarian torsion. Appendicitis should be suspected when symptoms are predominantly right-sided. Diffuse abdominal pain should prompt an evaluation for other life-threatening problems, including leaking abdominal aortic aneurysm, peritonitis, hemoperitoneum from ectopic pregnancy, and bowel obstruction.

Diagnostic Testing

Uncomplicated Diverticulitis

A clinical diagnosis of uncomplicated diverticulitis can be made in a patient in the appropriate age range who is exhibiting focal left lower quadrant pain and tenderness in the absence of symptoms or signs that suggest an alternative diagnosis. No mass or peritoneal irritation should be encountered on examination, and the patient should otherwise appear well. If the patient fits this clinical picture, treatment can be initiated on an empirical basis. No laboratory tests or diagnostic imaging is required. Ancillary tests are performed primarily to exclude alternative diagnoses. When the diagnosis is unclear, studies to exclude gynecologic, renal, hepatic, biliary, or pancreatic disease may be indicated, depending on the patient’s presentation and degree of distress. Computed tomography (CT) of the abdomen should be considered for older patients and immunocompromised patients to exclude the possibility of a subtle presentation of complicated diverticulitis.

Complicated Diverticulitis

Abdominal Computed Tomography. Abdominal CT, with oral and/or colonic contrast (American College of Radiologists [ACR] appropriateness score = 9) or without contrast (ACR appropriateness score = 6), is the preferred method of evaluation of complicated diverticulitis. CT has the advantage of evaluating the colon and the structures around it, so it can facilitate the diagnosis of diverticulitis and simultaneously evaluate the extent of disease. Findings on CT consistent with diverticulitis include the presence of diverticula, inflammation of pericolonic fat, thickening of the bowel wall to more than 4 mm, free abdominal air, and abscesses (Fig 85.1). CT also can help make an alternative diagnosis when diverticulitis is absent. Sensitivity and specificity for diverticulitis range from 69% to 95% and from 75% to 100%, respectively. Marked bowel wall thickening associated with diverticulitis looks like cancer; contrast enema or endoscopy may be required to differentiate the two.

Barium Enema. Although asymptomatic diverticuli do not typically require investigation, a double-contrast barium examination with plain radiography can be used if imaging is desired. Barium should, however, be avoided in the setting of diverticulitis. The potential for preexisting occult perforation and subsequent risk of barium peritonitis limits its usefulness.

Water-Soluble Contrast Enema. Although now rarely used, a plain radiography, water-soluble contrast enema is the preferred method of imaging if a plain radiography study is needed in the acute setting. Because contrast material usually collects only in the intestinal lumen, plain radiography contrast enemas provide less information than CT about the extent of disease outside of the colon.

Ultrasonography. An ultrasound examination can detect various pathologic features characteristic of diverticulitis, including fluid collections around the colon, thickened hypoechoic bowel wall, and hyperechoicity adjacent to the bowel wall that suggests pericolonic inflammation. Diverticula can occasionally be visualized by ultrasound examination. As is often the case, the sensitivity of ultrasound imaging for these findings varies significantly with the experience of the operator. Currently, the role for ultrasonography in the evaluation of diverticulitis is not well defined.
Colonoscopy. Colonoscopy is limited in the acute setting by its more invasive nature, risk of perforation, and logistics of arranging this procedure emergently.

Plain Radiography Without Contrast. Plain radiographs of the abdomen are not likely to be helpful in the diagnosis of diverticulitis unless intestinal obstruction or perforation is suspected.

Management

Diverticulosis

It is recommended that patients with diverticulosis be placed on a high-fiber diet to reduce abdominal symptoms. The formerly common advice—to avoid foods that may obstruct diverticula, such as nuts, small seeds, and popcorn—has been discredited.

Uncomplicated Diverticulitis

Despite accumulating evidence that antibiotics may not provide benefit in the treatment of uncomplicated diverticulitis, enough controversy persists to recommend that they still be used. Uncomplicated diverticulitis in an immunocompetent, non–older patient can be managed on an outpatient basis with oral antibiotics covering gram-negative aerobic and anaerobic bacteria (Box 85.3). Patients may be placed on a liquid diet for comfort, although this is not mandatory. NSAIDs or narcotics are appropriate for pain control. Evidence supporting a high-fiber diet for prevention of diverticulosis is not mandatory. It is recommended that patients with diverticulosis be placed on a high-fiber diet to reduce abdominal symptoms. The formerly common advice—to avoid foods that may obstruct diverticula, such as nuts, small seeds, and popcorn—has been discredited.

Complicated Diverticulitis

Patients with complicated diverticulitis should be hospitalized and treated with IV antibiotics and bowel rest. Emergent surgical consultation is indicated for patients with peritonitis or perforation. Newer techniques that use a laparoscopic approach have supplanted open surgical techniques in some patients. Continuing clinical decline, sepsis resistant to medical management, or a high level of suspicion for carcinoma warrants urgent surgical consultation. Small abscesses may be treated with IV antibiotics alone (see Box 85.4), whereas larger abscesses are drained percutaneously or surgically. Bowel obstruction during an attack of diverticulitis is usually self-limited and resolves with conservative management. Chronic recurrent diverticulitis can result in strictures. Fistulae are usually repaired surgically but are typically not emergent.

Definitive Management

It is not known whether medical or dietary treatment is of benefit in diverticulitis. The only proven way to eradicate diverticula is to remove the affected segment of colon surgically. Most patients who recover from their first attack of diverticulitis are likely to remain asymptomatic for many years. According to some experts, younger patients (ie, <40 years) should undergo elective resection after their first bout of diverticulitis because of concerns about a higher risk for a second attack, but this recommendation has been questioned by recent studies. Most resections can be done laparoscopically with a single-stage procedure (no colostomy). Estimates on the recurrence of diverticular disease after resection vary, ranging from 3% to 27%, with up to 25% of patients continuing to have chronic intermittent pain, despite surgery.

Disposition

Younger and immunocompetent patients with uncomplicated diverticulitis may be sent home on oral antibiotics with referral for follow-up evaluation in 2 to 3 days to determine the success of treatment. Approximately 90% of patients will have a successful resolution with this approach. Patients not improved at follow-up should undergo diagnostic imaging to look for an abscess and should be hospitalized for IV antibiotic therapy. Of patients treated medically for their first attack of uncomplicated diverticulitis, 95% remain symptom-free for the next 2 years, and 80% to 90% remain symptom-free permanently. Although it was recommended in the past that all patients should undergo an evaluation for colon cancer when the acute episode has resolved because of the high incidence of coexistent cancer, recent evidence has suggested that this is not necessary.

All patients with complicated diverticulitis require hospitalization for IV antibiotic therapy and bowel rest. Most patients (65%–85%) recover with medical management alone; the rest require surgical intervention. Outcomes generally are good, with mortality rates ranging from 1% to 6% for all patients, increasing to 12% to 18% for patients requiring surgery.

LARGE BOWEL OBSTRUCTION

Principles

Large bowel obstruction (LBO) is much less common than small bowel obstruction, but LBO is a more ominous condition because it is frequently associated with malignant disease. Of all operative cases involving LBO in the United States, 50% are the result of colorectal cancer, and up to 20% of patients with colon cancer will develop acute obstruction. Adhesions, a common cause of small bowel obstruction, cause only a small number of LBOs. Other
causes of LBO include volvulus, diverticular disease, fecal impaction, strictures (often related to inflammatory bowel disease or chronic colon ischemia), adhesions, hernias, and pseudo-obstruction. Most causes are managed surgically, but pseudo-obstruction responds well to medical management alone.

When mechanical obstruction is caused by an obstructing lesion, inside the bowel (carcinoma) or outside the bowel (diverticular abscess, volvulus), the bowel becomes increasingly dilated with air and fluid that cannot be passed distally. As the distention increases, intraluminal pressure increases. When intraluminal pressure approaches systolic blood pressure, blood flow to the bowel wall is compromised, and edema sets in, with subsequent transudation of fluid into the lumen. Transudation along with decreased reabsorption of intraluminal fluid leads to dehydration. Eventually, as arterial flow to the bowel wall is compromised, ischemia and gangrene develop. The translocation of bacteria from a compromised bowel can lead to sepsis. Perforation of the bowel wall follows if the process is not interrupted.

Pseudo-obstruction, also termed Ogilvie’s syndrome, occurs through a completely different mechanism. Pseudo-obstruction is defined as LBO in which no obstructing lesion can be identified. This condition is usually found in patients with significant acute comorbid conditions. Patients typically have a history of spine or retroperitoneal trauma, severe electrolyte disturbances, or narcotic exposure. The mechanism is believed to involve malfunction of autonomic control of the bowel. The pathophysiologic changes observed with pseudo-obstruction are the same as those described for mechanical obstruction.

Clinical Features
The typical presenting complaints in LBO are abdominal pain, abdominal distention, obstipation, and vomiting. The time frame within which these symptoms develop varies in accordance with the rapidity of onset of the obstruction. LBO associated with a volvulus can develop rapidly, whereas obstruction from cancer tends to be gradual. Patients seen later in the course of obstruction may be significantly dehydrated. Fever or tachycardia should prompt an investigation for gangrene and perforation. A palpable abdominal mass may represent a tumor, abscess, or simply a distended bowel. A rectal examination is helpful to look for an obstructing rectal mass or large volume of hard stool in the rectal vault consistent with fecal impaction.

Differential Diagnosis
The most common causes of LBO are colorectal cancer (53%), volvulus (17%), diverticulitis (12%), and compression from metastatic disease (6%). Other, less common causes are strictures, incarcerated hernia, fecal impaction, adhesions, and pseudo-obstruction.

Diagnostic Testing
Laboratory Tests
Electrolyte measurements may be helpful in guiding fluid and electrolyte replacement therapy. An elevated white blood cell (WBC) count should raise suspicion for gangrenous bowel, whereas anemia suggests the possibility of colorectal cancer.

Imaging Studies
Plain Radiography. A distended colon is the hallmark of LBO (Fig. 85.2), although the small bowel may be distended as well if the ileocecal valve is incompetent. In some cases, a gas-filled
small bowel may obscure visualization of the colon, leading to the misdiagnosis of small bowel obstruction. A cecal diameter exceeding 12 cm is associated with a higher risk of perforation, but perforation has been known to occur at smaller diameters. The actual location and cause of the LBO are usually not evident on plain films.

Computed Tomography. CT is a valuable tool for determining the cause of the obstruction, especially if the cause is a diverticular abscess or intussusception. CT has the ability to locate the obstructing lesion in 96% of cases. It typically is less helpful in pseudo-obstruction, in which colonoscopy or a water-soluble contrast enema study is needed to make the diagnosis.

Colonoscopy and Water-Soluble Contrast Enema. Patients in whom the cause of obstruction is not known and who are not candidates for urgent surgical intervention should undergo a water-soluble contrast enema study or colonoscopy to determine the cause of the obstruction. This diagnostic strategy is much more accurate in ruling out pseudo-obstruction than imaging.

Management
Management in the ED is directed at relief of symptoms. Rehydration, electrolyte replacement, and pain management are the first concerns. Gastric decompression with a nasogastric tube may be helpful in cases in which vomiting is prominent or when there is evidence of fluid or gas buildup in the small intestine; regardless, the patient should be kept NPO. Antibiotics are indicated if gangrene or perforation is suspected (see Box 85.4). Definitive management depends on the cause of the obstruction. Select diverticular abscesses may be drained percutaneously, whereas a sigmoid volvulus or pseudo-obstruction can be decompressed endoscopically. Diverticular disease and sigmoid volvulus eventually necessitate an elective surgical procedure to prevent recurrence, although this can often be delayed. Carcinoma, cecal volvulus, strictures, intussusception, adhesions, and hernias are primarily dealt with surgically. In malignant obstruction of the left colon, placement of a stent can be done palliatively or as a bridge to surgery.

As long as the possibility of perforation is not an immediate concern, pseudo-obstruction is managed for the first 24 hours with bowel rest, hydration, and management of any acute comorbid conditions. If the colon fails to decompress, colonoscopic or pharmacologic intervention (eg, neostigmine) may be attempted, with surgery reserved for refractory cases.

Disposition
Most cases of LBO require procedural intervention (surgical, endoscopic, or percutaneous) to achieve resolution. All patients require hospitalization and consultation with a specialist capable of performing the appropriate procedure. Emergent surgical consultation is warranted for patients with evidence of gangrenous bowel or perforation.

**VOLVULUS**

Principles
Volvulus of the colon occurs when a loop of bowel twists and obstructs the intestinal lumen. Volvulus accounts for 1% to 7% of all LBOs. Volvulus occurs in all age groups, but older adults (mean age, 60–70 years) are affected most often. One-third of cases in the developed world involve institutionalized patients. Most cases are divided roughly equally between the sigmoid colon and cecum, although volvulus can occur in all other areas of the colon. Sigmoid volvulus typically is a disease of older adults. Mortality rates with sigmoid volvulus exceed 50% in patients with gangrenous bowel. In the absence of gangrenous bowel, the risk of death is less than 5%.

Sigmoid Volvulus
The anatomic requirement for a sigmoid volvulus is a long redundant section of sigmoid that is attached to the abdominal wall by a narrow strip of mesentery. The narrow attachment allows the mesentery to twist on itself, thereby obstructing the intestinal lumen. After the colon twists on itself, the proximal colon continues to force gas and liquid into the obstructed segment, causing a sometimes massive dilation of the distal colon. Electrolyte disturbances can occur secondary to third spacing, and respiratory compromise occasionally occurs from massive abdominal distention. If the condition is left untreated, the vascular supply can become compromised, resulting in gangrene and perforation. In one series, approximately 10% of patients developed gangrene of the affected segment.

The exact precipitator of an acute episode of volvulus is not clear. A high-fiber diet has been implicated. Chronic constipation has been associated with volvulus, but it is unclear how the two conditions are related. Residents of long-term care facilities and patients with neurologic or psychiatric disease are predisposed to sigmoid volvulus, possibly as a result of alterations in colonic motility. No association with previous surgery has been observed.

Cecal Volvulus
As in sigmoid volvulus, a mobile segment of cecum is a prerequisite to the disease. This mobility seems to be a result of a congenitally incomplete fusion of the cecal mesentery to the posterior abdominal wall. Cadaver studies have shown that 11% to 25% of the adult population have ceca that are mobile enough to cause torsion. Despite these findings, sigmoid volvulus is relatively rare, implying that another coexisting factor such as trauma, adhesions, or malignancy must be present. The tendency for cecal volvulus may be related to maneuvering room available for the colon within the abdomen. Women seem to be at a higher risk for cecal volvulus during pregnancy, presumably because of crowding of the abdominal cavity by the enlarged uterus. Even in pregnancy the condition is still rare, occurring in approximately one per million pregnancies. Gangrene of the bowel is common with cecal volvulus, occurring in 20% of patients.

Clinical Features
Sigmoid Volvulus
The hallmark of sigmoid volvulus is the triad of abdominal pain, distention, and constipation. The extent to which the sigmoid colon can twist on itself varies, so the presentation can vary from subtle to dramatic. The clinical picture may range from one of minor abdominal discomfort that has been present for many days to an acute onset of severe abdominal pain associated with gross abdominal distention and unstable vital signs. Sometimes, the diagnosis of sigmoid volvulus is not made until the patient has been hospitalized for some time, up to an average of 3 or 4 days between symptom onset and diagnosis in some studies.

The physical examination may reveal a distended tympanic abdomen, often with most of the distention in the upper abdomen but primarily on one side. Patients may look remarkably well for the amount of distention that is encountered. Significant abdominal pain, fever, lack of bowel sounds, peritonitis, or cardiovascular instability suggests gangrenous bowel and should
prompt immediate surgical consultation. The absence of these findings does not exclude gangrene, however, and the duration of symptoms alone is not predictive of gangrene.

Cecal Volvulus

Although the vast majority of patients (90%) have abdominal pain, the clinical triad of abdominal pain, distention, and constipation is inconsistent. Patterns of presentation vary on a spectrum similar to that for sigmoid volvulus. Vomiting is seen in only 50% of patients.

Differential Diagnosis

Any process that causes LBO may mimic volvulus, including neoplastic disease, paralytic ileus, toxic megacolon, and pseudo-obstruction.

Diagnostic Testing

Sigmoid Volvulus

The diagnosis of sigmoid volvulus can be made with plain radiographs in most cases. A grossly distended loop of colon lacking haustral markings is typical and is seen just as often on the right side of the abdomen as on the left (Fig. 85.3). The bowel may have the appearance of a bent inner tube. Free air may be seen on an upright chest radiograph or lateral decubitus radiograph of the abdomen in patients who have a perforation. Gas backing up into the rest of the colon may obscure the typical appearance of sigmoid volvulus on plain radiographs, leading to a significant number of nondiagnostic study results. Cecal volvulus and bowel obstruction from other causes may have a similar radiographic appearance. When the diagnosis is in doubt, contrast enema may be helpful. Contrast material fills up the colon to the tapering point of torsion, giving a bird’s beak appearance to the column of contrast material (Fig. 85.4). Sigmoidoscopy is diagnostic in many cases, visualizing a spiral sphincter-like twist in the colonic mucosa. CT scanning, when used, is also highly accurate, but most diagnoses can be made without it.

Cecal Volvulus

Plain radiographs often are helpful in establishing a diagnosis of cecal volvulus, but the findings are not definitive in up to 50% of cases. The cecum should be markedly dilated and may contain an air-fluid level. The small bowel often is distended as well. In contrast, with sigmoid volvulus, the distal colon should have a paucity of gas (Fig. 85.5). The classic coffee bean sign, a large oval gas shadow with a line down the middle representing bowel bent over on itself, may be seen in the midabdomen. Free air suggests perforation and necessitates emergent surgical consultation. A common mistake is misinterpreting the plain radiograph as showing a sigmoid volvulus. If the diagnosis is unclear, a contrast enema is helpful in showing the site of torsion. Ultrasound imaging generally is unhelpful. On CT, a mesocolon whirl sign (Fig. 85.6) may be seen, indicating a twisted segment of mesentery; particularly helpful are multiplanar reconstructions. In many cases, cecal volvulus is definitively diagnosed only at surgery.

Management

Sigmoid Volvulus

Although spontaneous reduction of a sigmoid volvulus can occur, it is infrequent enough to mandate a proactive approach to treatment. If clinical evidence of gangrenous bowel is lacking, endoscopic detorsion should be attempted by an experienced operator, during which a lubricated flexible tube is inserted through the
obstruction. With decompression of gas and liquid stool, the bowel is able to undergo self-detorsion. Endoscopic decompression is successful in 50% to 90% of cases. If the patient has a gangrenous bowel or the volvulus does not respond to endoscopic decompression, surgery is indicated. Recurrence rates are estimated at 60%; elective resection of the redundant sigmoid is recommended after resolution of the acute episode. The mortality rate for sigmoid volvulus is 20% overall and exceeds 50% in the subpopulation of patients with gangrene.

Cecal Volvulus

The proximal nature of the cecum makes it unavailable for endoscopic manipulation; cecal volvulus requires resection of the cecum by an open or laparoscopic technique. Recurrence is rare after resection.

Disposition

All patients with volvulus require hospitalization for invasive intervention.

INTUSSUSCEPTION

Principles

Intussusception is considered the primary cause of bowel obstruction in children and the second most common cause of acute abdomen in children after appendicitis. The peak incidence in pediatric patients is between 4 and 10 months of age. In contrast, adult intussusception is rare, accounting for only 5% of all intussusceptions and is more often associated with coexisting neoplasms and malignancies. In adults, the condition occurs over a wide variety of ages, with a mean age at presentation of 65 years. The male-female ratio is approximately 3:1 in children, but the gender prevalence is equal in adults.

Intussusception has gained public attention because of its association with the rotavirus vaccine. The well-documented benefits of rotavirus vaccine have been found to outweigh the possible small risks of intussusception.

The exact mechanism of intussusception is unknown, but it is believed that a lead point lesion changes the motility properties of the intestine, allowing a proximal segment to invaginate into a more distal segment. As peristaltic activity pushes the invaginated segment along with its mesentery and mesenteric blood vessels distally down the bowel, the blood supply to the segment can be compromised, and ischemia may occur. Edema associated with the intussusception can lead to a mechanical obstruction of the bowel. If not treated promptly, a reduced blood supply can lead to bowel necrosis and perforation. The most common locations are at the junctions between freely moving segments, retroperitoneally, or adhesional fixed segments.

In most infants, the intussusception involves the ileum invaginating through the ileocecal valve into the cecum. Of intussusceptions in children, 95% are idiopathic. In the pediatric population, there is a common association with hyperplasia of Peyer’s patches secondary to viral infections; 80% to 90% of adult intussusceptions have an identifiable cause. Adult intussusceptions that occur in the small bowel are caused by benign lesions 60% of the time; the remainder are caused by malignancy (30%) or are idiopathic (10%). In contrast, most colonic intussusceptions (60%–65%) are caused by malignancy.

Clinical Features

Intussusception manifests in one of two patterns, acute or subacute. In pediatric intussusception, the pattern is acute, with
abrupt onset of intermittent, colicky, abdominal pain, which can cause episodes of crying and pulling the knees up. In adults, the most common is that of acute partial intestinal obstruction, because less than 20% of intussusceptions cause complete obstruction. The typical presenting complaint is abdominal pain, with vomiting and rectal bleeding as the next most common complaints. Constipation may also be present. The abdomen may be distended, and bowel sounds often are decreased. A mass is seldom palpated; the classic triad of abdominal pain, mass, and hemepositive stools noted in children is found in less than 50% of pediatric intussusceptions and is rarely found in adults. Similarly, currant jelly stools and altered mental status are rare presentations and often occur late in the disease progression. The presence of crying, abdominal mass, pallor, and vomiting are clinical indicators of pediatric intussusception. Individually, each variable is not helpful but, when all four are present, there is a high probability of the disease.26

The subacute presentation is much more subtle, with intermittent abdominal pain for months. The diagnosis usually is made only when the pain becomes unrelenting or has been recurrent enough to prompt imaging.

Differential Diagnosis

The differential diagnosis includes other causes of bowel obstruction.

Diagnostic Testing

Ultrasound Examination

Ultrasonography is helpful in detecting intussusception but is not as useful as CT in excluding other diagnoses. For facilities that have skilled ultrasound technicians available, ultrasound is the primary diagnostic test used in the pediatric population.25 A transverse view of the intussusception has a doughnut or target shape, with multiple concentric rings. A longitudinal view has an ultrasound appearance similar to that of a kidney (so-called pseudo–kidney sign), with a bright central area often surrounded by a darker outer layer (Fig. 85.7).

Plain Radiography

Plain radiography is a reasonable screening test in a patient suspected of having bowel obstruction, but usually shows only nonspecific large bowel dilation.

Computed Tomography

CT is usually the most useful test for adult patients with suspected intussusception but may not detect the actual intussusception in up to 50% of cases. The characteristic findings on CT include a target- or sausage-shaped soft tissue mass with a layering effect, with mesenteric vessels within the intestinal lumen (Fig. 85.8).

Barium Enema

Although a barium enema study can demonstrate intussusception and even reduce it, it is a less desirable study than CT or ultrasound examination for initial diagnosis. It should not be performed in patients suspected of having a bowel perforation.

Colonoscopy

Colonoscopy is helpful in defining the lesion causing intussusception but does not usually detect the intussusception itself.

Management

In pediatric intussusception, the treatment of choice for the stable child is a trial of pneumatic or hydrostatic reduction when appropriate radiologic facilities are available. This may prevent the need for surgery, and the cause is usually benign. Reduction of pediatric intussusception is sufficient treatment in 80% of patients.

Surgery is required in most cases of adult intussusception. Because of the high incidence of malignancy and the concerns of spreading malignant cells from potentially malignant lead points, reduction often is not attempted in adults before surgical exploration. Surgical treatment is recommended for patients who are acutely ill, who have evidence of perforation, for whom nonoperative reduction is unsuccessful, who need evaluation or resection of a pathologic lead point, or who are treated in a setting where radiologic facilities are unavailable. ED care is supportive and aimed at optimizing fluid status, decompressing the stomach with a nasogastric tube, recognizing perforation, administering antibiotics if compromised bowel is suspected, and securing surgical consultation in the appropriate time frame. Occasionally,
INFLAMMATORY BOWEL DISEASE

Principles

Inflammatory bowel disease (IBD) includes two clinically similar but distinct diseases, Crohn’s disease (CD) and ulcerative colitis (UC). Both diseases are characterized by chronic and unpredictable relapsing inflammation of the gastrointestinal tract. It is estimated that more than 1 million people in the United States are affected by IBD. Cases are divided approximately equally between CD and UC, with a combined annual incidence of 10 cases/100,000. The prevalence is more common in North America and Europe and is much less common in Asian and African populations. IBD can occur at all ages, with a peak onset at 15 to 30 years of age. Up to 25% of IBD cases develop during childhood or adolescence, whereas 10% to 15% of patients with IBD will receive their diagnosis when older than 60 years. The long-term management of IBD is a complex stepwise process that involves multiple medications and surgery. The goals of ED evaluation are to (1) recognize potential new cases of IBD, (2) consider and exclude serious complications in patients with IBD, and (3) identify patients with IBD who need in-hospital care. Treatment plans are best developed in consultation with a physician experienced in the long-term management of IBD.

IBD is thought to develop as a result of dysregulation of the immune system, driven by an immune response to normal intestinal flora in a genetically susceptible host. In essence, it is the loss of the normal tolerance to these bacteria. Increased familial prevalence is found in patients diagnosed early in life, whereas environmental modifiers are thought to influence later onset. Chronic inflammation of the gut results, which can lead to complications and extraintestinal manifestations.

Ulcerative Colitis

UC causes inflammation and ulceration throughout the colon and rectum but spares the small intestine. Inflammation is more superficial than in CD. Typically, the inflammation exists as one continuous lesion originating in the rectum and extending a variable distance into the colon, although cases of discontinuous disease (so-called skip lesions) similar to that in CD have been reported in UC. The concordance rate between identical twins is low (6%–14%), suggesting that factors other than genetics are involved. A change to a Western lifestyle is associated with increased risk, and stress can trigger exacerbations.

Inflammatory arthropathies and primary sclerosing cholangitis are the most common extraintestinal manifestations of UC. Other extraintestinal manifestations include involvement of the skin, eyes, and bones.

Crohn’s Disease

CD may affect any part of the gastrointestinal tract, usually the distal small intestine and proximal colon and, less commonly the esophagus, duodenum, or stomach. Because of the transmural inflammation, the development of intestinal strictures, abscesses, or fistulae to adjacent organs are potential complications. Concordance between identical twins is 45% to 50%, and genetic mutations have been identified, suggesting a strong genetic predisposition that is modified by other factors. Although the onset of the disease can occur at any time of life, CD affects primarily younger patients, with onset of disease typically in the teens and 20s. Pediatric-onset disease is more often severe and extensive, with a higher chance of upper gastrointestinal tract disease compared to adult-onset disease.

Extraintestinal manifestations, such as arthritis, aphthous stomatitis, uveitis, erythema nodosum, and ankylosing spondylarthropathy, occur more often in CD than UC.

Clinical Features

Typical presenting complaints in patients with IBD include abdominal pain and tenesmus, with bloody diarrhea. Patients with CD may have a history of nocturnal diarrhea, which helps differentiate CD from patients who have IBS. The physical examination may reveal significant abdominal tenderness or an abdominal mass representing an abscess. Patients with CD may have fissures, ulcerated hemorrhoids, strictures, or cutaneous abscesses around the anus. Onset of symptoms usually occurs before the age of 30 years, although the diagnosis can be difficult to make in the early stages. The most useful clues of possible IBD in children with abdominal pain are diarrhea, growth and pubertal delay, weight loss, rectal bleeding, pallor, fatigue, perianal skin tags, fistulae or abscesses, and family history of IBD.

Patients often come to the ED with a known diagnosis of IBD and worsening abdominal symptoms. A common reason for relapse is interruption of the medications that have kept the disease in remission. Many patients become complacent during

Disposition

All patients diagnosed with intussusception require hospitalization. Operative mortality tends to be minimal.

INFLAMMATORY BOWEL DISEASE

Principles

Inflammatory bowel disease (IBD) includes two clinically similar but distinct diseases, Crohn’s disease (CD) and ulcerative colitis (UC). Both diseases are characterized by chronic and unpredictable relapsing inflammation of the gastrointestinal tract. It is estimated that more than 1 million people in the United States are affected by IBD. Cases are divided approximately equally between CD and UC, with a combined annual incidence of 10 cases/100,000. The prevalence is more common in North America and Europe and is much less common in Asian and African populations. IBD can occur at all ages, with a peak onset at 15 to 30 years of age.

Up to 25% of IBD cases develop during childhood or adolescence, whereas 10% to 15% of patients with IBD will receive their diagnosis when older than 60 years. The long-term management of IBD is a complex stepwise process that involves multiple medications and surgery. The goals of ED evaluation are to (1) recognize potential new cases of IBD, (2) consider and exclude serious complications in patients with IBD, and (3) identify patients with IBD who need in-hospital care. Treatment plans are best developed in consultation with a physician experienced in the long-term management of IBD.

IBD is thought to develop as a result of dysregulation of the immune system, driven by an immune response to normal intestinal flora in a genetically susceptible host. In essence, it is the loss of the normal tolerance to these bacteria. Increased familial prevalence is found in patients diagnosed early in life, whereas environmental modifiers are thought to influence later onset. Chronic inflammation of the gut results, which can lead to complications and extraintestinal manifestations.

Ulcerative Colitis

UC causes inflammation and ulceration throughout the colon and rectum but spares the small intestine. Inflammation is more superficial than in CD. Typically, the inflammation exists as one continuous lesion originating in the rectum and extending a variable distance into the colon, although cases of discontinuous disease (so-called skip lesions) similar to that in CD have been reported in UC. The concordance rate between identical twins is low (6%–14%), suggesting that factors other than genetics are involved. A change to a Western lifestyle is associated with increased risk, and stress can trigger exacerbations.

Inflammatory arthropathies and primary sclerosing cholangitis are the most common extraintestinal manifestations of UC. Other extraintestinal manifestations include involvement of the skin, eyes, and bones.

Crohn’s Disease

CD may affect any part of the gastrointestinal tract, usually the distal small intestine and proximal colon and, less commonly the esophagus, duodenum, or stomach. Because of the transmural inflammation, the development of intestinal strictures, abscesses, or fistulae to adjacent organs are potential complications. Concordance between identical twins is 45% to 50%, and genetic mutations have been identified, suggesting a strong genetic predisposition that is modified by other factors. Although the onset of the disease can occur at any time of life, CD affects primarily younger patients, with onset of disease typically in the teens and 20s. Pediatric-onset disease is more often severe and extensive, with a higher chance of upper gastrointestinal tract disease compared to adult-onset disease.

Extraintestinal manifestations, such as arthritis, aphthous stomatitis, uveitis, erythema nodosum, and ankylosing spondylarthropathy, occur more often in CD than UC.

Clinical Features

Typical presenting complaints in patients with IBD include abdominal pain and tenesmus, with bloody diarrhea. Patients with CD may have a history of nocturnal diarrhea, which helps differentiate CD from patients who have IBS. The physical examination may reveal significant abdominal tenderness or an abdominal mass representing an abscess. Patients with CD may have fissures, ulcerated hemorrhoids, strictures, or cutaneous abscesses around the anus. Onset of symptoms usually occurs before the age of 30 years, although the diagnosis can be difficult to make in the early stages. The most useful clues of possible IBD in children with abdominal pain are diarrhea, growth and pubertal delay, weight loss, rectal bleeding, pallor, fatigue, perianal skin tags, fistulae or abscesses, and family history of IBD.

Patients often come to the ED with a known diagnosis of IBD and worsening abdominal symptoms. A common reason for relapse is interruption of the medications that have kept the disease in remission. Many patients become complacent during

Disposition

All patients diagnosed with intussusception require hospitalization. Operative mortality tends to be minimal.
Toxic Megacolon

Toxic megacolon is a pathologic dilation of the colon resulting from inflammation of the smooth muscle layers of the intestine, which leads to muscle paralysis, dilation, and eventually perforation if left untreated. The hallmark of toxic megacolon is colonic dilation in a systemically toxic patient with a known inflammatory condition of the colon. Systemic toxicity differentiates toxic megacolon from other disorders that cause colon dilation, including mechanical obstruction, pseudo-obstruction, and congenital or acquired megacolon (Fig. 85.9).

The triggering event may be recent ingestion of anticholinergics, antimotility agents, narcotics, or antidepressants. Patients usually have experienced severe symptoms of colitis for several days before the onset of toxic megacolon. Patients have more than 10 stools daily, continuous bleeding, abdominal pain, distention, and acute, severe toxic symptoms, including fever and anorexia.

Extraintestinal Manifestations

Extraintestinal manifestations include inflammatory conditions of the skin (eg, erythema nodosum, pyoderma gangrenosum), eyes (eg, episcleritis, scleritis, uveitis), joints (eg, arthritis, spondylitis), bone (eg, osteoporosis), spine (eg, ankylosing spondylitis), and liver (eg, primary sclerosing cholangitis). Thromboembolic events in IBD patients are often overlooked and underdiagnosed, affecting the venous and arterial systems. The inflammatory process initiates clotting and decreases the activity of anticoagulation mechanisms. There is a 60% increase in thromboembolic disease (eg, deep venous thrombosis [DVT], pulmonary embolism [PE]) compared to that in the general population. Cerebrovascular complications including cerebral sinus thrombosis are more frequent during bouts of inflammation. There is also an increased risk of ischemic heart disease and mesenteric ischemia. Peripheral neuropathy is the most common neurologic complication of IBD, thought to be due to immune-mediated changes, metronidazole toxicity, and vitamin deficiency. Chronic inflammation may be the most important driver of these complications in IBD.

Differential Diagnosis

Symptoms and signs are protean and overlap with those of many common abdominal conditions, including appendicitis, infectious colitis, ischemic colitis, radiation colitis, diverticular disease, cancer, and bowel obstruction. In children, the differential diagnosis can also include Henoch-Schönlein purpura, celiac disease, and functional abdominal pain. Intestinal infections commonly mimic the symptoms of IBD, including those caused by Escherichia coli O157:H7, Clostridium difficile, and amoeba.

Diagnostic Testing

Endoscopic evaluation with biopsy is required to confirm the diagnosis. Diffuse, continuous mucosal inflammation involving the rectum and extending to a point more proximal in the colon are suggestive of UC, whereas a complex or fistulizing lesion, involvement of the upper gastrointestinal tract, skip lesions, or granulomata are suggestive of CD. No specific laboratory tests to diagnose IBD are available, although recent tests targeting antibodies to Saccharomyces cerevisiae (ASCA) or antineutrophil cytoplasm (P-ANCA) help differentiate between CD and UC. An elevated ASCA value is more suggestive of CD, whereas an elevated P-ANCA level is more likely UC. Electrolyte abnormalities may be caused by severe diarrhea, or anemia may occur from gastrointestinal blood loss.

An elevated C-reactive protein level or erythrocyte sedimentation rate can be useful for categorizing the severity of the disease and differentiate it from IBS, because IBS is not associated with elevations in these inflammatory biomarkers. Intestinal infections should be excluded to diagnose IBD definitively. Because intestinal infections commonly mimic the symptoms of IBD, it is suggested that new patients should have microbiologic studies for bacterial infection, including E. coli O157:H7, C. difficile, and amoeba. These tests are negative in patients with IBD. Established patients who have recently been hospitalized or been on antibiotics should be tested for C. difficile. Stool studies contain fecal leukocytes, but cultures and microbiologic studies should be normal.

Plain radiographs should be limited to patients suspected of having complications such as bowel obstruction, toxic megacolon, or perforation. For diagnosing toxic megacolon, plain radiographs are diagnostic and show a colon with a diameter of 6 cm or larger, although this feature may not be present in early stages (see Fig. 85.9). CT of the abdomen and pelvis with at least IV contrast, and preferably with oral contrast if tolerated, is the best study to evaluate extraluminal complications (ACR appropriateness score = 8). Magnetic resonance imaging (MRI) enterography (with oral contrast; ACR appropriateness score = 6) can locate affected bowel segments and identify fistulae, stenoses, and abscesses. It also has the advantage of not using radiation, which is preferred in children and is also a consideration in individuals likely to undergo multiple imaging studies over time.
Management

Medical management is the mainstay of therapy for most patients with IBD. Treatment is typically driven by the severity of symptoms. However, newer treatment models have recommended symptom remission and endoscopic remission to prevent complications from disease progression due to chronic inflammation. Treatment regimens should be discussed with a gastroenterologist. The dosages given in this section are suggested induction doses.

In general, patients are maintained on oral aminosalicylates, also known as 5-aminosalicylic acid (5-ASA) agents while symptomatic and then placed on steroids if symptoms recur. Once remission is achieved, steroids are discontinued and the patient is once again maintained on 5-ASA agents. If remission is not achieved with steroids, other agents such as antimetabolites and immunosuppressants are used. The choice of agents depends on classification of the disease as mild, moderate, or severe (Box 85.5). Bowel rest is not beneficial, except as preparation for surgical intervention. Surgery is reserved for patients with severe disease who do not respond to medical therapy or for those with serious complications.

5-ASA agents are the first line of therapy for mild to moderate disease and for maintenance therapy. These agents can be administered orally or rectally if the disease is in or near the rectum. Sulfasalazine, starting at 1 g every 6 hours for adults and 40 to 60 mg/kg/day 48h for pediatric patients, is one of the original drugs in this category. Its use is limited by sulfa toxicity at higher doses and has side effects that may include vomiting, anorexia, and headache; rarely it may result in bone marrow suppression, pancreatitis, hepatotoxicity, anemia, and interstitial nephritis. A newer 5-ASA derivative, mesalamine, 1 g every 6 hours PO or 2 to 4 g rectally as a daily dose at bedtime, has less toxicity, allowing higher dosages.

Antibiotics may be used for the treatment of IBD, but their use is controversial. Evidence supporting antibiotic use is stronger for CD than UC. In patients with active luminal CD or fistulizing CD, or CD patients who do not tolerate 5-ASAs or have not shown improvement within 4 weeks of 5-ASA therapy, metronidazole, 500 mg PO or IV every 8 hours and ciprofloxacin, 400 mg PO or IV every 12 hours, are used most commonly, with some evidence suggesting that tobramycin or rifaximin may be beneficial as well.61

Oral corticosteroids are used for patients with moderate to severe disease or patients whose IBD is unresponsive to a 5-ASA agent. Steroids should be tapered when remission is achieved to avoid typical side effects. IV steroids are reserved for hospitalized patients with severe disease. Prednisone is often initiated and then tapered, with induction dosing of 40 to 60 mg daily. Budesonide, 9 mg daily, a newer oral steroid, is degraded on its first pass through the bloodstream and has fewer systemic side effects. Prolonged use of steroids can lead to gastrointestinal mucosal injury, problems with wound healing, osteopenia with fractures, and frank osteonecrosis that may be evident only on MRI.36

The immunomodulating drugs azathioprine, starting at 2 mg/kg/day, and 6-mercaptopurine, starting at 1 mg/kg/day, are used in patients resistant to other therapies or to wean steroid-dependent patients. Patients on these medications should be assessed for bone marrow suppression and pancreatitis.

The immunosuppressant agent cyclosporine, 2 to 4 mg/kg IV daily, is used for severe cases, such as fulminent colitis, often when patients are not surgical candidates. Although most patients tolerate it well, cyclosporine has significant potential toxicity, including myelosuppression, electrolyte disturbances, and hepatic toxicity and nephrotoxicity. Opportunistic infections, including Pneumocystis pneumonia, have been known to occur.

Infliximab, an antibody to tumor necrosis factor alpha (TNF-α), is used in advanced cases, with induction doses of 5 mg/kg IV. It generally has a benign side effect profile but carries an increased risk of opportunistic infections, including tuberculosis and fungal infections. Serum sickness will be experienced by 1% to 2% of patients, with symptoms including arthralgias, myalgias, fevers, and rash.60

Surgery is reserved for patients with severe disease refractory to medical management and for patients with complications such as intestinal obstruction, significant bleeding, abscess, or fistula. Up to 25% of patients with UC will eventually require colectomy for uncontrolled disease. A colectomy is curative for UC and improves quality of life, but there is no curative surgery for CD. Extraintestinal manifestations usually respond to therapy for intestinal disease.

Treatment for toxic megacolon includes fluid hydration, IV corticosteroids, antibiotics covering bowel flora (see Box 85.4), and evaluation for potential intestinal infections, especially in immunocompromised patients. Hypokalemia or hypomagnesemia should be corrected if present because it can exacerbate.

---

**BOX 85.5**

**Disease Severity Criteria in Inflammatory Bowel Disease**

**ULCERATIVE COLITIS**

**Mild Disease**
- Fewer than four stools/day
- Stools may contain some blood
- No systemic signs of toxicity (eg, fever, tachycardia, anemia, elevated erythrocyte sedimentation rate)

**Moderate Disease**
- More than four stools/day
- Minimal signs of toxicity

**Severe Disease**
- More than six bloody stools/day
- Signs of systemic toxicity

**CROHN’S DISEASE**

**Mild to Moderate Disease**
- Patient ambulatory and able to eat
- No dehydration
- No toxicity
- No significant abdominal pain or mass
- Weight loss of 10%

**Moderate to Severe Disease—Any of the Following**
- Mild disease that has failed to respond to treatment
- Patient may have some systemic toxicity, significant weight loss, anemia
- Fever, some abdominal pain or tenderness, intermittent nausea or vomiting

**Severe Disease**
- Persistence of symptoms during corticosteroid or biologic (eg, infliximab) therapy
- High fever, persistent vomiting
- Intestinal obstruction
- Rebound tenderness
- Cachexia
- Abscess

colonic aneurysms and is responsible for 10% of deaths after aortic dissection, and up to 60% of operations for ruptured abdominal aortic aneurysm. CI is also seen as a complication after major cardiovascular surgery.47 CI complicates up to 7% of elective operations on the colon, in the setting of collagen vascular disease, hematologic disorders, long-distance running, or cocaine abuse. Medications associated with CI include digoxin, pseudoephedrine, and sumatriptan.45 CI is diagnosed about 3.5-fold more frequently in patients with IBS. Although less common, it is important to consider that distally obstructing lesions of the colon can also theoretically raise intracolonic pressure and cause CI by reducing colonic blood flow. CI is also seen as a complication after major cardiovascular surgery.47 CI complicates up to 7% of elective operations on the aorta and up to 60% of operations for ruptured abdominal aortic aneurysms and is responsible for 10% of deaths after aortic replacement.

**COLONIC ISCHEMIA**

**Principles**

Colonic ischemia (CI) is the most common intestinal ischemic disorder and yet remains poorly understood.44-46 The incidence of CI is 1/2000 hospitalizations, occurring more often in women than men. Its presentation overlaps with that of many other abdominal diseases and is difficult to diagnose without endoscopic visualization of the colonic mucosa. Although 90% of CI cases occur in patients older than 60 years, the condition can occur in any part of the colon, including the rectum, but for unknown reasons it occurs most often (80%) in the left colonic segment. Isolated right colon ischemia (IRCI) with no other segments involved occurs in only 10% to 25% of cases and has a worse outcome than CI affecting any other region on the colon.44 Patients with IRCI more frequently suffer from atrial fibrillation, coronary artery disease, and chronic kidney disease. Because the superior mesenteric artery (SMA) supplies the right side of the colon as well as the small intestine, it is thought that IRCI could be the heralding presentation of an acute SMA occlusion.

CI represents a spectrum of disease whose manifestations vary with the extent of the ischemic insult. In most cases, the ischemic episode is self-limited, and the condition resolves completely with conservative therapy but, in one-third of patients, a prolonged or severe insult results in scarring or stricture formation of the colon and chronic symptoms. If the ischemia is transmural, gangrene and intestinal perforation are possibilities.

**Clinical Features**

The presentation of CI typically involves the acute onset of mild crampy abdominal pain in the left lower quadrant, with abdominal distention and blood in the stool. IRCI presents less frequently with bloody stools.46 The typical patient has had recent surgery or significant medical illness. Nausea and vomiting can occur with obstruction secondary to a stricture or ileus. Tenderness over the affected colon may be present but often is not dramatic. Peritoneal findings, fever, and an elevated WBC count suggest gangrenous bowel and perforation. Toxic megacolon is a recognized complication. Without surgical intervention, fulminating gangrenous CI can lead to perforation, multiorgan failure, and death.46

**Differential Diagnosis**

The symptoms of CI are nonspecific and overlap with those of numerous other disorders, including IBD, diverticulitis, infectious proctitis, and other causes of nonprofuse, lower gastrointestinal bleeding. If strictures are present, the possibility of diverticulitis or colon cancer should be considered.

**Diagnostic Testing**

**Laboratory Tests**

No sensitive or specific biochemical markers for CI are recognized, although abnormalities such as elevated serum lactate and alkaline phosphate levels may be present once irreversible damage has occurred. A complete blood count to exclude and look for a leukocytosis suggestive of perforation is recommended. Serum electrolyte levels should be checked if diarrhea or vomiting has been severe or prolonged. Blood and WBCs in the stool are common findings in several of the entities that present similarly to CI, including IBD and infectious colitis. Unfortunately, the definitive diagnosis of CI is rarely made in the ED.

**Imaging Studies**

**Plain Radiography.** Plain radiographs often show only non-specific dilated bowel. Findings specific for CI occur in approximately 20% of patients. Classic findings are (1) intraluminal prominences, known as thumbprinting, which represent submucosal hemorrhage and swelling, and (2) wall thickening and ahastral segments. Air in the portal venous system or bowel wall suggests imminent intestinal infarction.
Computed Tomography. Although CT does not allow the definitive diagnosis of CI, it is useful to support the clinical suspicion, assess the extent of colon involvement, diagnose potential complications, and exclude other disorders. CT features suggestive of CI include thumbprinting, wall thickening, and luminal narrowing and inner wall hypoperfusion, the so-called double halo sign (Fig. 85.10).

Barium Enema. Thumbprinting is detected more often by barium enema than by plain radiography. However, barium enemas have largely been replaced by colonoscopy.

Colonoscopy. Emergent colonoscopy should be performed after the colon is prepped with an enema. Colonoscopy with biopsy is the preferred method to diagnose CI because it visualizes the abnormal colonic mucosa, and biopsy specimens help differentiate between cancer and other nonischemic causes of colitis. Colonoscopy can also detect a necrotic bowel by its distinct cyanotic or black appearance. If colonoscopy is delayed, pathologic findings may be missed on colonoscopy in up to one-third of cases. Colonoscopy is also helpful in making a definitive diagnosis of CI. In those with continuing significant symptoms, colonoscopy is usually curative.

Radiation Proctocolitis

Principles

Radiation proctocolitis (RP) is a common side effect of radiation therapy, occurring in 50% to 75% of patients receiving radiation to the pelvis. The radiation dose is a major determinant of the severity of acute and late toxicity. The disease has two distinct presentations, acute and chronic. Acute RP begins during or shortly after a course of radiation therapy, typically within 6 weeks, is usually easily diagnosed, and is self-limited. Chronic RP occurs in 5% to 10% of patients who have undergone pelvic radiation therapy and begins any time after the end of radiation therapy, which can make the diagnosis challenging.

Radiation is an effective treatment for neoplastic disease, but also damages rapidly growing intestinal epithelium. The mucosal injury leads to loss of normal barrier function, and luminal microbes trigger an acute inflammatory response, leading to further mucosal damage. Impaired recognition of bacterial translocation worsens the inflammatory response and can lead to chronic inflammatory changes, such as strictures, fibrosis, and ischemia. The fixed portions of the colon, the cecum and rectum, are at a greater risk of receiving higher doses of radiation.

Acute Radiation Proctocolitis

The intestinal epithelium normally is sloughed and replaced at a rapid rate. After the start of radiation therapy, growth of replacement epithelium is slowed, but sloughing continues at the preexposure rate. This mismatch leads to gaps in the epithelium, which over time coalesce into ulcerations. In addition, edema and inflammatory changes of the submucosa cause excessive mucus secretion and bleeding. When radiation therapy has ended, the cycle of damage stops, and healing occurs over the next few weeks.
Chronic Radiation Proctocolitis

The pathologic mechanism in chronic RP is entirely different and results from a progressive endarteritis, with abnormal tissue collagen deposition. The affected intestine has a decreased microvascular density, with subsequent decreased perfusion. Over time, the affected bowel gradually becomes more ischemic, leading to ulceration, scarring, and narrowing of the bowel lumen.

Clinical Features

Acute RP manifests with abdominal and rectal pain, diarrhea, bleeding, and tenesmus. Onset during the course of radiation therapy, typically after several treatments, suggests the diagnosis. Symptoms can be severe and can lead to therapy interruption or treatment plan alteration in 5% to 15% of cases. Chronic RP has a more insidious onset, with symptoms including ulcerative disease, stricture, obstruction, fistulae, and bowel perforation or may present similarly to acute RP. Bleeding is common but usually is not hemodynamically significant. A decreased caliber of stool, with increased straining or constipation, suggests a stricture. Fistulae can develop between the affected bowel and any adjacent organ, but the most common site is rectovaginal.

Some patients with acute or chronic RP may exhibit anal sphincter dysfunction. Fecal incontinence has been reported in up to 20% of patients, which can be devastating to quality of life.

Differential Diagnosis

In chronic RP, the possibility that symptoms are a result of recurrence of the initial malignancy or a new malignancy induced by radiation exposure should be entertained. Symptoms of chronic RP are generally clinically indistinguishable from those of other causes of bowel inflammation, including IBD, infectious colitis, and ischemic colitis.

Diagnostic Testing

Acute RP is a clinical diagnosis based on the development of typical symptoms in the setting of radiation therapy. Further evaluation is usually not warranted.

Chronic RP is a diagnosis of exclusion. Endoscopy can be suggestive, revealing pale, thickened, and friable mucosa, with prominent telangiectasias. Biopsy specimens often show only nonspecific chronic inflammation.

Management

Acute Radiation Proctocolitis

Treatment of acute RP is symptomatic, and a therapeutic plan should be developed in conjunction with the patient’s radiation therapist. Measures to improve the patient’s nutritional status should be considered. Steroid enemas (eg, hydrocortisone enema, 100 mg bid) to reduce inflammation, sucralfate enemas (20 mL of a 10% suspension in water bid), and water-absorbing stool softeners to reduce mucus-containing diarrhea are helpful. Reduction of the daily radiation dose also can reduce symptoms significantly. Butyrate enemas may accelerate healing in acute RP because butyrate is a short-chain fatty acid, which is the preferred luminal nutrient for colonocytes.

Chronic Radiation Proctocolitis

Chronic RP treatment also is symptomatic. If rectal involvement is significant, stool softeners, analgesics, antiinflammatory agents (eg, sulfasalazine, mesalazine), and sucralfate enemas are helpful. Metronidazole, 500 mg orally tid given for 4 weeks has been shown to be beneficial in reducing rectal bleeding, mucosal ulcers, and diarrhea when added to the antiinflammatory therapy of mesalazine and betamethasone enemas. Continued rectal bleeding can be controlled with topical formalin or laser photocoagulation. Minimally symptomatic strictures can be managed initially with stool softeners and enemas, which may be enough to reverse the edema and lessen the extent of narrowing. Fistulae and significant strictures generally require surgical repair. Approximately 20% of all patients with chronic radiation injury to the intestinal tract require some type of surgical intervention. Biopsy specimens from ulcerations associated with chronic injury should be obtained to exclude malignancy.

Disposition

Suspected perforation requires emergent surgical consultation, and signs of bowel obstruction should prompt urgent surgical consultation. Unless symptoms are severe, patients with acute or chronic RP can usually be managed on an outpatient basis under the care of their radiation therapist or gastroenterologist. With acute disease, symptoms typically resolve weeks after radiation treatments have been completed. Mild chronic disease typically resolves with medical therapy, but more severe symptoms often require intervention.

KEY CONCEPTS

Irritable Bowel Syndrome
- IBS is a chronic disorder affecting 10% to 15% of people that presents with abdominal discomfort (bloating) associated with changes in the form or frequency of stool and is relieved by defecation.
- IBS is treated with diet, behavioral, and pharmacologic therapies.
- New or atypical symptoms in a patient with known IBS should prompt an evaluation for other abdominal pathology.

Diverticular Disease
- Colonic diverticula are present in 10% of people older than 45 years and 80% of people older than 85 years. They can cause bleeding (diverticulosis) or become obstructed and inflamed (diverticulitis).

Large Bowel Obstruction
- Over 50% of cases of LBO are caused by malignancies; other common causes include volvulus, diverticular disease, and fecal impaction.

CHAPTER 85: QUESTIONS & ANSWERS

85.1. Which of the following symptoms is most typical for irritable bowel syndrome (IBS)?
A. Anorexia
B. Fever
C. Nocturnal pain
D. Occasional hemocolit-positive stools
E. Pain relieved by defecation

**Answer:** E. Pain relieved by defecation is typical for IBS. The other listed findings, along with significant abdominal tenderness, would be unusual. IBS can be constipation- or diarrhea-predominant.

85.2. Which of the following statements regarding diverticular disease of the colon is true?
A. Diverticular bleeding is usually painful.
B. Double-contrast barium enema is the emergency department (ED) test of choice for confirmation.
C. It accounts for 40% of lower gastrointestinal (GI) hemorrhage
D. Most patients with diverticulosis develop diverticulitis.
E. The most common site of fistula formation is adjacent bowel.

**Answer:** E. Diverticular bleeding is typically painless. The most common site of fistula formation is the bladder. Most patients with diverticulosis may have asymptomatic. Double-contrast barium enema is the outpatient test of choice for the diagnosis of diverticulitis, but is not indicated in the acute setting.

85.3. A 59-year-old man with a past history of diverticulosis and diverticulitis presents with his second episode of left lower quadrant (LLQ) abdominal pain. He is afebrile, and laboratory examination is remarkable for a leukocytosis of 13,800/mm³. Physical examination reveals moderate LLQ tenderness without masses or rebound. A computed tomography (CT) scan of the abdomen reveals a small (4 cm) abscess adjacent to the sigmoid colon,
with moderate diverticulosis-diverticulitis. Which of the following would be the most appropriate treatment?
A. Admission for intravenous antibiotics
B. Confirmation with double-contrast barium enema
C. Discharge on oral antibiotics with 2-day follow-up
D. Radiology consultation for percutaneous drainage
E. Surgical consultation for laparotomy

Answer: A. Abscesses smaller than 5 cm are typically treated with intravenous antibiotics followed by an outpatient oral regimen. Larger abscesses may be drained surgically or percutaneously.

85.4. What is the most common cause of large bowel obstruction?
A. Adhesions
B. Colon cancer
C. Diverticulitis
D. Intussusception
E. Volvulus

Answer: B. Colon cancer accounts for 53% of cases. Volvulus and diverticulitis account for 17% and 12% of cases, respectively. Extrinsic compression from cancer accounts for 6% of cases. Adhesions, unlike for small bowel obstructions, are a rare cause of large bowel obstructions.

85.5. Which of the following is a key difference between sigmoid and cecal volvulus?
A. Clinical presentation
B. Incidence of constipation versus diarrhea
C. Incidence of spontaneous detorsion
D. Preferred method of detorsion
E. Radiographic appearance

Answer: D. Both types of volvulus present with acute or subacute onset of the triad of abdominal pain, distention, and constipation. Spontaneous detorsion is not typical. Sigmoid volvulus is very amenable to endoscopic detorsion, whereas cecal volvulus typically requires surgical detorsion.

85.6. Which of the following statements regarding intussusception is true?
A. Bowel obstruction typically occurs.
B. CT scans have a high sensitivity for detection of intussusception.
C. Most adult cases involve the large bowel.
D. Most adult cases require surgery.
E. Most children have a causative lesion.

Answer: E. Most children have a causative lesion. In contrast to children, most adult cases have a causative pathologic lesion, usually located within the small bowel. Complete obstruction occurs in less than 20% of cases. CT scans may miss as many as 50% of cases of intussusception. Surgery is usually required FOR adults with intussusception.

85.7. A 29-year-old woman presents with a 4-month history of intermittent abdominal pain with bloating and diarrhea. The diarrhea has been watery, nonbloody, and often nocturnal. Physical examination is remarkable for mild diffuse abdominal tenderness and brown, guaiac-positive stool. Rectal examination also demonstrates a small anal fissure at the 3-o’clock position. Laboratory evaluation is remarkable only for a normocytic anemia with a hemoglobin level of 11.5 g/dL. The diagnosis would most likely be confirmed by which of the following?
A. Colonoscopy
B. CT scan of the abdomen
C. Erythrocyte sedimentation rate
D. Mesenteric angiography
E. Response to a high-fiber diet

Answer: A. This presentation is typical for inflammatory bowel disease. Nocturnal diarrhea, blood in the stool, and presence of an eccentric (nonposterior midline) anal fissure argue against IBS or a benign diarrhea. Ischemic colitis would be unlikely in this age group. Endoscopy with biopsy would be the diagnostic intervention of choice.

85.8. Which of the following statements regarding colonic ischemia is true?
A. CT scanning of the abdomen is diagnostic
B. It is rarely associated with bloody stool.
C. It is typically due to nonocclusive disease.
D. It typically occurs without predictable antecedent events.
E. Specific serum biomarkers may be helpful.

Answer: C. Colonic ischemia is typically due to nonocclusive microvascular disease. It occurs due to low-flow conditions related to congestive heart failure (CHF), renal failure, hypovolemia, or recent illness or surgery. Bloody stools are predictable. It may also occur in younger patients with collagen vascular disease, hematologic abnormalities, or cocaine abuse. There are no sensitive or specific laboratory tests and, although sometimes suggestive, CT scanning primarily rules out other processes.

85.9. Which of the following is not a diagnostic criteria for IBS?
A. Abdominal pain of at least 3 days/month for the previous 3 months
B. Association of discomfort with altered stool frequency
C. Association of discomfort with altered stool form
D. Nocturnal pain
E. Pain relief with defecation

Answer: D. Night time symptoms are generally absent in irritable bowel syndrome and should prompt the provider to look for other possible causes.

85.10. A 38-year-old man presents with his second episode of diverticulitis with LLQ abdominal pain and constipation. Symptoms largely resolve after hydration and conservative management in the ED. Which of the following is true?
A. A high-fiber diet will exacerbate symptoms acutely.
B. Abdominal CT scanning should be considered.
C. Colonoscopy is required.
D. Surgical referral is indicated.
E. Trace occult blood would be consistent with diverticulitis.

Answer: D. Surgery is reserved for patients with recurrent episodes and ongoing pain.

85.11. A 60-year-old woman without significant medical history presents with 3 days of LLQ pain without fever. The physical examination reveals moderate tenderness to the LLQ. No mass is felt. Pelvic and rectal examinations, including stool guaiac testing, show no abnormality. What is the most appropriate next step in this patient’s management?
A. Admit for colonoscopy.
B. Discharge the patient with oral antibiotics.
C. Obtain a CT scan of the abdomen and pelvis.
D. Perform an ultrasound of the pelvis.
E. Request urgent general surgery consultation.

Answer: C. Obtain a CT scan of the abdomen and pelvis.
85.12. What would be the most appropriate management strategy for the patient in question 85.11 if she were taking immunosuppressant medications for advanced rheumatoid arthritis?
A. Admit for colonoscopy.
B. Discharge the patient with oral antibiotics.
C. Obtain a CT scan of the abdomen and pelvis.
D. Perform an ultrasound of the pelvis.
E. Request urgent general surgery consultation.

**Answer:** C. Patients taking immunosuppressant medication who present with diverticulitis may have much more serious disease than their physical examination would suggest. Such patients are at higher risk for bowel perforation by the time of presentation and should undergo more extensive evaluation to exclude complications.

85.13. A patient with known ulcerative colitis presents with abdominal distention and significant dehydration. The patient appears acutely ill. A plain film of the abdomen shows a dilated segment of transverse colon measuring 8 cm in width. All of the following are indicated except:
A. Antibiotics covering bowel flora
B. Intravenous corticosteroids
C. Intravenous rehydration
D. Serum chemistry measurements
E. Urgent colonoscopy to decompress the bowel

**Answer:** E. This patient has toxic megacolon, which does not generally have an obstructing lesion.

85.14. A patient who presents with the acute onset of tenesmus and blood-streaked stool reports that he is currently undergoing pelvic radiation for prostate cancer. What is the most appropriate next step in the patient’s management?
A. Admit for colonoscopy.
B. Develop a care plan with the patient’s radiation therapist.
C. Refer to a gastroenterologist for proctoscopy.
D. Perform anoscopy.
E. Send a stool sample to test for *Clostridium difficile*.

**Answer:** B. Acute radiation proctocolitis generally responds well to lowering the dose of radiation and symptomatic treatment. It generally resolves shortly after radiation treatments are completed. Those coordinating the patient’s radiation treatment should be made aware of this complication.
Disorders of the Anorectum

Wendy C. Coates

CHAPTER 86

PRINCIPLES

Patients visit the emergency department (ED) with a variety of anorectal complaints. Sensitivity and a professional demeanor should be maintained in interactions with these patients, who may find it difficult to discuss historical details openly and to describe physical complaints related to this area of the body and its function.

The anorectum begins at the rectosigmoid junction at the level of the third sacral vertebra (S3), the rectum follows the sacral curvature for 12 to 15 cm and then sharply turns posteriorly and inferiorly at the puborectalis muscle (Fig. 86.1). Here the anal canal begins its 4-cm course to the anus, which is supported by three muscle groups—levator ani and internal and external anal sphincters. Anal valves and crypts with mucous glands for lubrication are located 2 cm proximal to the anal verge at the dentate line. Proximal to the crypts are the columns of Morgagni, where the epithelium of the anal canal changes from pink columnar (as in the rectum) to squamous.

The superior, middle, and inferior hemorrhoidal arteries provide the blood supply to the anorectum. They arise from the inferior mesenteric, internal iliac, and internal pudendal arteries, respectively. The superior hemorrhoidal veins drain into the portal system, and the inferior hemorrhoidal veins drain into the caval system. Lymphatic drainage is to the inferior mesenteric nodes above the dentate line and to the inguinal nodes from all areas of the anorectum.

Sympathetic and parasympathetic nervous systems function together to retain the contents of the rectum until evacuation is desired. Sympathetic fibers from L1 to L3 (upper rectum) and presacral nerves (lower rectum) inhibit the contraction of rectal smooth muscle, and L5 fibers cause the internal sphincter to contract. Elimination occurs when parasympathetic fibers from the anterior roots of S2 to S4 cause the rectal wall to contract and the internal sphincter to relax. Voluntary external sphincter control is mediated by motor branches of the pudendal nerve (S2, S3) and the perineal branch of S4. The levator ani is supplied by the pudendal nerve and pelvic branches of S3 to S4 fibers. Sensory perception of rectal distention relies on parasympathetic fibers from S2 to S4. The abundant sensory nerve endings of the distal anal epithelium transmit via the pudendal nerve.

Defecation begins as the rectum becomes distended, the internal sphincter relaxes, and stool enters the anal canal. At an appropriate time and place, the external sphincter is relaxed to complete the process of elimination. When voluntary straining is required, abdominal muscles contract, the rectal angle straightens, and the pelvic floor descends. To postpone defecation, the external sphincter contracts voluntarily, relaxing the rectal wall and quelling the urge to defecate unless there is an underlying sphincter disorder or an overwhelming volume of stool.

CLINICAL FEATURES

A history of anorectal and gastrointestinal (GI) symptoms and the presence of systemic disease elucidate the diagnosis of most anorectal disorders (Box 86.1; Fig. 86.2). Common complaints include bleeding, swelling, pain, itching, and discharge. History should include questions about onset, duration, quality, bowel habits (changes in color, frequency, or consistency of the stool and the presence of straining, flatus, and incontinence of solid or liquid stool); a history of radiation exposure or sexual practices is helpful in select cases. Underlying GI disorders (eg, Crohn’s disease, cancer, polyps) often produce atypical presentations. Patients with an underlying systemic disease such as AIDS, cancer, diabetes mellitus, and coagulopathy may develop more serious complications of standard anorectal conditions.

In patients presenting with rectal bleeding, the color, amount, and relationship to defecation are important factors in establishing the cause. Pain and bright red blood signify anal fissures or hemorrhoids. Fissure pain is sharp, sudden in onset, and not associated with swelling, whereas pain from a prolapsed or thrombosed hemorrhoid is gnawing, continuous, and of a more gradual onset. Painless rectal bleeding occurs with internal hemorrhoids, cancer, or precancerous lesions. Red blood on the toilet paper usually is caused by anal fissures or external hemorrhoids; however, minute quantities can result from any irritating condition. Bright red blood that drips into the toilet bowl or streaks around the stool is caused by internal hemorrhoids. Blood mixed with stool originates above the rectum, whereas melena indicates a more proximal source. Bloody mucus is associated with cancer, inflammatory bowel disease, and proctitis.

Patients who report a perianal swelling or have the sensation of rectal fullness often list hemorrhoids as their chief complaint. Painful swellings that bleed usually are thrombosed hemorrhoids, but abscesses, pilonidal disease, and hidradenitis suppurativa should be considered. Painless, itchy swellings may be caused by condylomata acuminata or secondary syphilis. A mass protruding through the anal orifice may signal rectal prolapse or cancer (Fig. 86.3).

Severe, episodic anorectal pain that is not associated with bleeding or swelling may represent proctalgia fugax or levator ani syndrome. Perianal itching (pruritus ani) is caused by any lesion that makes hygiene difficult or may be attributed to certain foods or medications.

The physical examination should ensure the patient’s comfort and privacy. With the patient in the left lateral decubitus position and covered with a sheet, inspect the buttocks and anal orifice. Note elements of personal hygiene and anatomic disruptions, such as fissures, skin tags, lesions, protruding hemorrhoids, and abscesses. Ask the patient to strain and note the integrity of the pelvic floor, prolapse of hemorrhoids, or rectal mucosa. A digital rectal examination begins by placing a well-lubricated gloved finger flat against the anal opening, exerting gentle pressure until the external sphincter relaxes, allowing the finger to enter the anus. Assess anal sphincter tone by asking the patient to squeeze the anal muscles against the examining finger. Accessible areas of the anorectum can be examined for masses and areas of tenderness with a circumferential sweep. The cervix or prostate can be palpated through the rectal wall. On withdrawal, the contents on the glove can be assessed for frank or occult blood, mucus, or pus.

Direct visualization of the anus may be accomplished by anoscopy. A lubricated anoscope is inserted into the anus, with the obturator in place. When the obturator is removed, the rectal mucosa can be viewed for sites of bleeding, hemorrhoids, masses, or abnormal tissue and finally the dentate line and anal epithelium.

**SPECIFIC ANORECTAL PROBLEMS**

**Hemorrhoids**

**Principles**

Hemorrhoids occur when the three anal vascular submucosal cushions become engorged. Blood supply arises from the arterial system, causing hemorrhoidal bleeding to be bright red. The muscularis submucosa cushions the anal canal during defecation and aids fecal continence. As the supportive tissue deteriorates, venous distention, prolapse, bleeding, and thrombosis may occur. Some controversy exists about whether straining and constipation cause these changes by producing venous backflow when intra-abdominal pressure increases. There is evidence that hemorrhoids are associated with traumatic deliveries.

Hemorrhoids are not varicose veins; they are normal structures that manifest symptoms when the muscularis submucosa weakens and the anal cushions are displaced distally. Conditions that increase sphincter tone correlate with a higher prevalence of hemorrhoids. Portal hypertension does not cause hemorrhoids in adults, although it appears to be a cause in children. Bleeding in patients with portal hypertension may be caused by rectal varices, which are vascular communications between the superior and middle hemorrhoidal veins.

**Clinical Features**

Patients often refer to any perianal condition as hemorrhoids. Bleeding with defecation is the most common complaint and, unless the hemorrhoids are thrombosed, it usually is painless. Patients report variable amounts of bright red blood on the toilet paper or toilet bowl. Many complain of swelling, itching, mucoid discharge, or a moist perianal area. History should address recent stool patterns, such as diarrhea or constipation, chronic medical problems, such as portal hypertension or bleeding disorders, and a dietary and family history. Frequent bowel movements, prolonged sitting, heavy lifting, and straining while defecating exacerbate symptoms.

Physical examination should ascertain the type and degree of hemorrhoids by visual inspection at rest and during straining. Nonprolapsing hemorrhoids can be visualized on anoscopy as a focus of bleeding or as they bulge when the patient is asked to strain. Anoscopy is painful and is not useful in cases of prolapsed or thrombosed hemorrhoids (Table 86.1). Table 86.2 shows the classification of hemorrhoids based on history, physical findings and reducibility.

**Management**

The symptoms of nonthrombosed external and nonprolapsing internal hemorrhoids can be ameliorated by a standard regimen,

Passage of stool is easier with stool softeners and a high-fiber diet. Nonsteroidal antiinflammatory drugs (NSAIDs) reduce pain. Softer stool. Mild oral analgesic agents such as acetaminophen or codeine (1.5%) gel may alleviate symptoms. Although not widely used, the purported effectiveness of this regimen is related to the ability of nifedipine to modulate resting sphincter tone and thereby reduce the associated pain and inflammation.

**Anal Fissures**

**Principles**

The development of an anal fissure is the most common cause of intensely painful rectal bleeding of sudden onset. A superficial tear in the anoderm results when a hard piece of feces is forced through the anus, usually in patients who are constipated. It is the most commonly encountered anorectal problem in pediatric patients, especially infants. Most fissures occur along the posterior midline, where the skeletal muscle fibers that encircle the anus are weakest. Anterior midline fissures are more common in women than in men. Fissures that occur elsewhere may be associated with systemic disease such as leukemia, Crohn’s disease, human immunodeficiency virus (HIV) infection, tuberculosis (TB), or syphilis. If not treated promptly, the classical so-called fissure triad of deep ulcer, sentinel pile, and enlarged anal papillae may develop (Fig. 86.5). A sentinel pile forms when the skin at the base of the fissure becomes edematous and hypertrophic; it can form a permanent skin tag and underlying fistulous tract.

**Clinical Features**

The patient with an anal fissure reports sudden, searing pain during defection that may be accompanied by a small amount of bright red blood in the stool or on the toilet paper. This is followed by a nagging, burning sensation caused by internal sphincter spasm. Subsequent bowel movements are excruciating, and the external sphincter may exhibit a reflex spasm. A physical examination must be performed cautiously to avoid further spasm and pain. The depth of the fissure, its orientation to the midline, and the presence of a coexisting sentinel pile should be noted. A digital rectal examination during an acute exacerbation often is impossible because of pain and sphincter spasm.

Management

Specific measures for the treatment of anal fissures are summarized in Box 86.3. Treatment with the WASH regimen (see Box 86.2) focuses on eliminating constipation with a bulking agent, stool softener, and high-fiber diet. Limited use of topical anesthetics may be helpful. Parental encouragement of pediatric patients helps prevent encopresis, which can result from a fear of painful bowel movements. Most acute uncomplicated fissures resolve in 2 to 4 weeks.

For adult patients with chronic anal fissures, application of various topical agents aimed at reducing sphincter pressures and local pain may be effective. Nitroglycerin ointment applied topically to the anoderm 2 or 3 times daily may relieve the pain but may cause a vasodilatory headache. Nifedipine gel (0.2%) in combination with lidocaine (1.5%) applied to the anal area twice daily is effective in promoting healing and reducing discomfort in the management of anal fissures by reducing anal canal pressures through local calcium channel blockade. Referral to a colorectal surgeon for definitive management may include injection of botulinum toxin, anal dilation, or sphincterotomy.

Abscesses and Fistulae

Principles

Anorectal abscesses and fistulae occur in otherwise healthy adults when the mucus-producing glands at the base of the anal crypts occlude and may herald the presence of inflammatory bowel disease, trauma, cancer, radiation injury, or infection (TB, lymphogranuloma venereum, actinomycosis). Common causative bacteria are Staphylococcus aureus, Escherichia coli, Streptococcus, Proteus, and Bacteroides.

Anorectal abscess is an acute disease that naturally progresses to fistula formation in the body’s attempt to drain the infection spontaneously. Symptoms vary depending on the site of infection, but incision and drainage constitute the curative treatment in all cases (Table 86.4). Delays may allow extension of the infection and eventual compromise of the sphincter mechanism. Adjunctive antimicrobial therapy is indicated in patients who are immunocompromised or diabetic or have valvular heart disease.

Sites of anorectal abscess formation are depicted in Fig. 86.6. The difficulty in diagnosis is that pain often precedes physical findings of a mass or fluctuance. One-third of patients with AIDS develop anorectal abscesses and fistulae, which may also direct antibiotic therapy. HIV-infected patients may have an incomplete fistulous tract, which impedes spontaneous drainage, highlighting the urgency of treating these patients promptly.

Management

Perirectal and Perianal Abscesses. Perirectal and perianal abscesses account for 40% to 45% of anorectal abscesses. They produce painful swelling at the anal verge that is worsened by defecating or sitting. Most patients are afebrile and have localized tenderness, erythema, swelling, and fluctuance. ED management by incision and drainage is usually possible in patients who do not have comorbidities (eg, diabetes mellitus, extremes of age, compromised immune status). Some patients may be unable to

**Fig. 86.5.** Lateral anal fissure. (Courtesy Dr. Gershon Effron, Sinai Hospital of Baltimore; from Seidel HM, et al, editors: Mosby's guide to physical examination, ed 4, St Louis, 1999, Mosby.)
Ischiorectal Abscess. One-fifth to one-quarter of abscesses form outside the sphincter muscles in the buttocks, and patients generally present complaining of severe pain. The diagnosis is obvious if an indurated mass is seen on the buttocks but is more difficult if the abscess is deep. Patients may have fever and leukocytosis. If there is no induration, ultrasound is useful to localize fluid collections and guide aspiration. Although many of these abscesses will require drainage performed with the patient under general anesthesia, superficial abscesses can be treated in the ED. The infection tracks cephalad and may appear to be a mass in the rectum; it can be confused with a thrombosed internal hemorrhoid. Patients report continuous rectal pressure and a throbbing pain exacerbated by defecation or sitting. They may have fever and leukocytosis. External evidence of inflammation may be lacking, but a rectal examination reveals an erythematous, indurated, and sometimes draining mass. Associated fistulae and inguinal lymphadenopathy are common. Surgical management is required to evaluate and treat the entire abscess and fistula network.

Supralevator Abscess. Accounting for less than 5% of abscesses, supralevator abscesses cause perianal and buttock pain associated with fever and leukocytosis. External evidence usually is absent, which often delays the diagnosis. Many patients are obese or have diabetes, Crohn’s disease, pelvic inflammatory disease, or diverticulitis. A tender mass may be palpated on rectal or pelvic examination. Emergent surgical treatment is indicated to drain the abscess and excise the fistulous network.

Postanal Abscess. These abscesses are uncommon and occur posteriorly to the rectum, deep to the external sphincter and inferior to the levator ani. Patients experience severe rectal discomfort and coccygeal pain. They usually are febrile and have continuous pain that does not change with position. A rectal examination is painful, and anal drainage is rare. Many of these abscesses are missed on initial presentation, and patients often return with draining abscesses that are managed surgically.

Horseshoe Abscess. A large, communicating, horseshoe-shaped abscess forms in the ischiorectal, intersphincteric, or supralevator space. Surgical management is necessary.

Necrotizing Infection. A delay in management of an anorectal abscess may lead to the destruction of tissue, especially in diabetic or immunocompromised patients. Widespread cellulitis, necrotic tissue, and gas on radiography suggest the possibility of necrotizing fasciitis, Fournier’s gangrene, or tetanus. Wide surgical debridement, broad-spectrum antibiotics with anaerobic coverage, and tetanus prophylaxis are indicated.

Fistulae. A fistula is a connection between two epithelium-lined surfaces and commonly develops in patients with abscesses; other causes include Crohn’s disease, trauma, foreign body reactions, TB, and cancer. The anorectal complaint may be the presenting symptom of the underlying disease. Patients notice a recurrent or persistent perianal discharge that becomes painful when one of the openings becomes occluded. A digital rectal examination may reveal a tract in the perineum or canal. Probing of fistulous tracts is not recommended because the danger of creating a new tract outweighs the benefit of identifying the path of the existing fistula. Spontaneous resolution of fistula-in-ano is rare. Although symptoms may resolve when antibiotics are administered, they commonly return as soon as therapy is discontinued; definitive treatment of the fistulous network at the time of incision and drainage of the abscess prevents ongoing progression of the disease continuum. Fistulectomy or application of fibrin glue are commonly accepted practices of colorectal surgeons. Non-surgical treatments that have been proposed for patients with Crohn’s disease include administration of infliximab or cyclosporine and hyperbaric oxygen therapy.

Pilonidal Disease

Principles

Abscesses containing hair and pus in the midline of the sacrococcygeal area afflict young adults with a 4:1 male predominance and are more common in obese and hirsute persons. The disease is rare in people older than 40 years, even for those who were affected in their youth, and should not be confused with anal fistulae, perirectal abscesses, hidradenitis suppurativa, or granulomatous
diseases (eg, syphilis, TB). It is believed to arise when bacteria enter the usually sterile hair follicle and produce inflammation and edema, thereby occluding the opening to the skin surface. The contents expand until the hair follicle ruptures, and the material spreads into the subcutaneous fatty tissue, where a foreign body reaction leads to abscess formation. The purulent material subsequently tracks to the presacral skin through an epithelialized tract. In those with chronic or recurrent disease, visible or palpable tracts containing hair and cellular debris may be identified.

Management

Treatment options vary, ranging from aspiration to extensive surgical excision. Supplementary antibiotics, such as cephalexin 500 mg qid, are indicated in cases accompanied by cellulitis, but are not effective as the sole treatment. ED management of pilonidal disease involves drainage of the acute abscess for relief of symptoms. Aspiration of pus plus antibiotics and referral to a surgeon in 1 week may promote faster recovery than incision and drainage. If incision and drainage is done, a longitudinal incision lateral to the midline prevents reaccumulation of debris and minimizes the inflammatory response in the midline. Recalcitrant disease may require surgical unroofing, marsupialization, or wide excision.

Hidradenitis Suppurativa

Principles

Perianal hidradenitis suppurativa is an infection of the apocrine glands. It is most common in young adults and is associated with poor skin hygiene, hyperhidrosis, obesity, acne, diabetes mellitus, and smoking. Occluded apocrine ducts may be infected with strains of *Staphylococcus*, *Streptococcus*, *E. coli*, or *Proteus*. Extension through the dermis spreads the infection to neighboring ducts and a network of sinus tracts, leading to extensive scarring.

Clinical Findings

Patients report one or more tender, draining pustules in the perianal area, which may be associated with fever, leukocytosis, and malaise. Local lymphadenopathy and surrounding cellulitis are common.

Differential Diagnosis

This condition commonly is misdiagnosed as pilonidal disease or fistula-in-ano. Other considerations in the differential diagnosis include sebaceous cysts, furuncles, granulomas (from TB or syphilis), and Crohn's disease.

Management

Treatment begins with careful attention to perianal hygiene, warm compresses, antibiotics (eg, cephalexin, 500 mg PO qid), and dietary modifications (avoidance of dairy products and foods with a high glycemic index). Drainage of isolated lesions may provide symptomatic relief, but the recurrence rate approaches 40%. Referral to a surgeon for wide excision of tissue involved in advanced chronic disease may be necessary.

Proctalgia

Anorectal pain (proctalgia) that does not arise from one of the organic disorders described earlier can be severe and difficult to treat. Two common causes are levator ani syndrome and proctalgia fugax. These disorders can be distinguished by their patterns of affliction. Other causes of pelvic pain, such as tumors, cauda equina syndrome and endometriosis, should be considered.

Levator Ani Syndrome

A constant dull pressure in the sacrococcygeal region precipitated by defecation or prolonged periods of sitting suggests levator ani syndrome. The patient usually has tenderness of the levator muscles, which may be firmly contracted on examination. No standard treatment regimen has been studied, but anecdotal reports indicate that sitz baths, levator ani muscle massage, and muscle relaxants can provide relief.

Proctalgia Fugax

Proctalgia fugax is an intensely painful spasm in the rectal area that begins abruptly and lasts up to 30 minutes, resulting from a sudden spasm of the levator muscle complex or sigmoid colon. Professionals, managers, perfectionists, and people who frequent the toilet are more likely to be affected. Symptoms begin abruptly during sleep, defecation, urination, or intercourse. The nature of the pain has been compared to that of charley horse (painful spasms in the leg muscles) and may radiate to the coccyx or perineum. Each patient has a unique but recurrent constellation of symptoms. Treatment includes a bowel-cleansing regimen, upward manual pressure on the anus, diazepam, and topical nitrates.

Fecal Incontinence

Principles

Fecal incontinence is an embarrassing condition that affects parous women, older adults, and patients with a variety of neurologic or traumatic disorders. The delicate balance among the pelvic floor muscles, sphincters, and anorectal sensation is disrupted in this condition. Complete incontinence is the inability to control passage of solid feces. Partial incontinence is characterized by loss of control of the passage of flatus or liquid feces.

Multiple causes of fecal incontinence have been described (Box 86.4). Liquid feces may seep around tumors or foreign bodies of the rectum or anal canal. Explosive diarrhea from laxative abuse, inflammation, or infection can temporarily overwhelm a normal sphincter mechanism. Encopresis may develop in young children experiencing emotional stress. In otherwise healthy children, sexual abuse involving the anus should be considered.

Clinical Features

The anorectum should be assessed for masses, hemorrhoids, evidence of previous surgery, and neuromuscular function. Neuromuscular causes of fecal incontinence are diagnosed by anorectal physiologic testing.

Management

The approach to management of fecal incontinence depends on the cause. In cases of transient incontinence caused by diarrhea, a high-fiber diet and brief therapy with loperamide, 2 mg, after each bowel movement, up to a maximum of 8 mg a day, can solidify stool and enhance rectal compliance. Kegel exercises, which contract the perineal muscles, biofeedback training, or surgical repair may be indicated.
Pruritus Ani

Principles

Patients with pruritus ani complain of an uncontrollable urge to scratch the perianal area. The condition is more common in the summer and is more noticeable at night. The sensation of itching arises when the richly innervated perianal skin becomes irritated. Vigorous scratching may result in excoriation. The most common cause is the presence of feces on the perianal skin. Conditions ranging from poor personal hygiene to anatomic disorders allow feces to accumulate. Obesity, deep perianal clefts, hair, hemorrhoids, skin tags, rectal prolapse, anal fissures, and fistulae make the area difficult to clean effectively. Decreased air circulation from wearing tight pants or undergarments of synthetic non-breathable fabric may exacerbate symptoms. The causes of pruritus ani are summarized in Box 86.5. The acronym “ITCH” categorizes typical causes—infection, topical irritants; cutaneous conditions and cancer; hypersensitivity to foods and drugs.  

Diagnostic Testing

Pinworms are most commonly found in young children and close contacts as well as in institutionalized patients. The organisms can be identified by applying transparent tape to the perianal area and attaching it to a glass slide. Visualization of eggs under the low-power objective of a microscope confirms the diagnosis.

Management

A careful history and physical examination will generally identify the cause of pruritus ani. Important considerations include hygienic care of the anus, coexisting anorectal or systemic conditions, diet, and sexual practices.

The first-line agent for pinworms is mebendazole (Vermox), 100 mg orally. An alternative agent is pyrantel pamoate (Antiminth), 1 g orally (11 mg/kg, to a maximum of 1 g for pediatric patients).17 A repeat dose may be needed in 2 weeks. Scabies and pediculosis pubis should be treated with 5% permethrin cream. Dermatitis caused by a fungal infection is characterized by sharply demarcated borders and is treated with clotrimazole 1% or nystatin cream. Definitive treatment of concomitant anorectal conditions (eg, fissures, fistulae, hemorrhoids, skin tags, rectal prolapse) can prevent recurrence of pruritus ani.

Underlying systemic diseases that have perianal manifestations should be treated. Patients should clean the area thoroughly with lukewarm water after each bowel movement and pat (rather than rub) dry with tissue that is free of chemical irritants. Loose-fitting underwear and exposure to fresh air may alleviate symptoms. The treatment of acute dermatitis includes a short course of topical

HPV, Human papillomavirus; HSV, herpes simplex virus; STD, sexually transmitted disease.
Sexually Transmitted Disease and Proctitis

Principles

Anorectal transmission of sexually transmitted disease (STD) is a concern in all sexually active patients with anorectal complaints, but especially in those with HIV. The history should ascertain whether sexual practices involve oral-anal contact or anal penetration and whether condoms are used. Education regarding transmission of STDs and the efficacy of barrier methods is an important means of public health prevention of disease. Semen contains the virus due to poor handwashing techniques. It is transmitted the virus. Occasionally Cases in which an infected person is changing a diaper and transmits the virus to the hands of the caregiver. The diagnosis can be made by visualizing spirochetes on dark-field microscopy from scrapings taken from the base of the ulcer.

Serologic testing is useful several weeks after the appearance of the chancre. Treponemal tests such as the fluorescent treponemal antibody (FTA) test yield a positive result earlier than the Venereal Disease Research Laboratory (VDRL) or rapid plasma reagin (RPR) test. If the chancre goes unnoticed, the patient may present with secondary syphilis, marked by a maculopapular rash that characteristically involves the palms and soles, and condyloma lata, a spirochete-laden, weeping, verrucous lesion in the perianal area that emits a foul odor. It is easily distinguishable from condyloma acuminatum, which has a drier, more keratinized appearance. Serologic testing results usually are positive. Tertiary syphilis is rare but may manifest as a rectal gumma with perianal pain and paralysis of the sphincters and may be mistaken for anal cancer.

Chancroid. Chancroid is caused by the gram-negative bacillus Haemophilus ducreyi; it begins as an inflammatory pustule or macule that ruptures to form an irregularly shaped ulcer. In several days, painful inguinal adenitis develops. Chancroid often is a diagnosis of exclusion.

Condyloma Acuminatum. Condyloma acuminatum (genital warts) is the most commonly encountered anorectal STD and is caused by human papillomavirus. The mode of transmission is primarily through sexual intercourse, but transmission can occur through close personal contact, as often happens in pediatric cases in which an infected person is changing a diaper and transmits the virus due to poor handwashing techniques. It is incumbent on the evaluating physician to consider sexual abuse in pediatric cases. Because half of HIV-positive patients have anal warts, HIV testing is recommended in patients with this diagnosis.

The pink to gray papilliform growths are a result of hyperplastic epithelial growth (Fig. 86.7). They may coalesce to form a massive patch that obscures the anal verge. Patients may be asymptomatic or report pruritus ani, a hemorrhoid, or bleeding. Evaluation can include anoscopy because the warts often grow within the anal canal. Failure to treat the internal lesions results in recurrence. The differential diagnosis includes condyloma lata (secondary syphilis) and squamous cell carcinoma. Preferred treatment is cryotherapy, but outpatient treatment with 0.5% podophyllotoxin solution or gel can be successful in limited cases.

Herpes Simplex Virus Infection. Herpes proctitis is caused by herpes simplex virus type 1 (HSV-1) and HSV-2. Symptoms appear 1 to 3 weeks after exposure. Those with proctitis may have rectal pain, bloody mucoid discharge, tenesmus, constipation, sacral paresthesias, and/or urinary difficulties. Examination may be impossible without anesthesia. Single or coalesced vesicles and ulcerations occur in the perianal area and rectum, and the rectal mucosa is erythematous, friable, and ulcerated. Chronic mucocutaneous HSV infection is considered diagnostic for AIDS. Definitive diagnosis with viral or immunofluorescent staining relies on collection of fluid and scrapings from the base of the vesicle.

Syphilis. Syphilis is caused by Treponema pallidum, a motile spirochete. During anal intercourse, the organism enters the rectal mucosa or anoderm and forms an ulcer (chancre) within 2 to 6 weeks. The chancre heralds the primary phase of syphilis and may resemble an anal fissure. Patients may experience discomfort during defecation, tenesmus, mucoid discharge, and inguinal adenopathy. Primary syphilis can be confused with lymphoma, but the diagnosis can be made by visualizing spirochetes on dark-field microscopy from scrapings taken from the base of the ulcer.
Ulcerative Lesions in HIV-Infected Patients. Most patients who are HIV seropositive have current or past infection with an STD, which may be the initial reason for seeking medical attention. Anorectal complaints in this population fall into three categories: (1) routine proctologic conditions, as seen in the general population; (2) STDs; and (3) opportunistic infections (Box 86.6). The treatment of routine conditions and common STDs is similar to that in other patients except that wound healing may be delayed.

**BOX 86.6**

Anorectal Lesions in the Patient With HIV Infection

**COMMON CONDITIONS**
- Anal fissure
- Abscess and fistula
- Hemorrhoids
- Pruritus ani
- Pilonidal disease

**COMMON STDs**
- Gonorrhea
- Chlamydial infection
- Herpes
- Chancroid

**ATYPICAL CONDITIONS**
- Infectious
  - TB, CMV infection, actinomycosis, cryptococcosis
- Neoplastic
  - Lymphoma, Kaposi’s sarcoma, squamous cell carcinoma
- Other
  - Idiopathic anal ulcer

CMV, Cytomegalovirus; HIV, human immunodeficiency virus; STD, sexually transmitted disease; TB, tuberculosis.

</table>
| LGV | Unilateral inguinal adenopathy | Doxycycline, 100 mg PO bid, for 21 days  
Fever, malaise | For pregnant patients or those allergic to tetracyclines—erythromycin, 500 mg PO qid, × 21 days |
| HSV infection | Rectal pain, tenesmus, constipation  
Bloody mucoid discharge  
Vesicles and ulcerations  
Fever, malaise, myalgias, paresthesias | First episode—acyclovir, 400 mg PO tid, 7–10 days or  
Acyclovir, 200 mg PO, 5×/day, for 7–10 days or  
Famciclovir, 250 mg PO bid, for 7–10 days or  
Valacyclovir, 1 g PO daily, for 7–10 days |
| Early (primary) syphilis (*Treponema pallidum*) | Chancre  
Tenesmus, pain, mucoid drainage  
Inguinal lymphadenopathy | Benzathine penicillin G, 2.4 million units IM, once |
| Chancroid (*Haemophilus ducreyi*) | Inflammatory lesion progresses to ulcer  
Inguinal adenitis—bubo | Azithromycin, 1 g PO once, or Ceftriaxone, 250 mg IM once, or Ciprofloxacin, 500 mg PO bid, for 3 days or  
Erythromycin, 500 mg PO tid, for 7 days |
| Idiopathic (usually HIV-positive) | Eccentric, deep, poor-healing, multiple lesions | Symptomatic relief or surgical referral |
| **NONULCERATIVE CONDITIONS** | | |
| Condylomata acuminata (HPV) | Keratinized vegetative growths in anus or skin  
Asymptomatic, pruritus ani, or bleeding | Podophilo, 0.5% topically, or cryotherapy |
| Gonorrhea (*Neisseria gonorrhoeae*) | Pruritus ani  
Tenesmus  
Purulent yellow discharge | Ceftriaxone, 250 mg IM once, or Cefixime, 400 mg PO, once |
| Chlamydial infection (*Chlamydia trachomatis*) | Mucoid or bloody discharge  
Tenesmus | Azithromycin, 1 g PO once, or Doxycycline 100 mg PO bid, for 7 days |
| Syphilis (secondary) | Maculopapular rash  
Condyloma lataum | Benzathine penicillin G, 2.4 million units IM, once |

be considered. The health care provider should report STDs and new diagnoses of HIV infection in accordance with state and local health department regulations.

In immunocompromised patients, the differential diagnosis of ulcerative anorectal lesions should include opportunistic infections, lymphoma, and Kaposi’s sarcoma. Patients with AIDS often exhibit idiopathic anal ulcerations with pain and bleeding. Before this diagnosis is made, other possible causes of the lesions must be considered (see Box 86.6). Symptomatic relief can often be achieved with the WASH regimen (see Box 86.2), but recalcitrant lesions may require surgical excision.

Radiation Proctitis

Radiation-induced injury of the rectum is often caused by treatment of gynecologic, urologic, and GI malignancies. Immediate radiation proctitis usually is self-limited and responds to symptomatic treatment. Delayed radiation proctitis can manifest for up to 2 years after the exposure.

Signs and symptoms of radiation proctitis include bleeding ranging in severity from spotting to hemorrhage, tenesmus, diarrhea, pain, fistula-in-ano, and rectal strictures. Diagnosis is achieved by rectal mucosal biopsy, a procedure best performed with the patient under sedation or anesthesia.

Treatment regimens include supportive therapy and the use of antiinflammatory agents, botulinum toxin injection, enemas with short-chain fatty acids, oral sucralfate therapy, hyperbaric oxygen therapy, and sclerosing therapy. 1 When a patient with suspected radiation proctitis presents to the ED, initial measures should focus on pain management while coordinating a care plan with the primary physician.

Rectal Prolapse

Rectal prolapse, or procidentia, is a disease of persons at the extremes of age. Prolapse is complete if all bowel layers protrude and incomplete if only the mucosal layer is involved. In adults, complete procidentia is most common among older women and is caused by a laxity of attachment structures; it often is accompanied by uterine prolapse or cystocele. Patients report an anal mass that protrudes during defecation, coughing, or sneezing.

Findings may include fecal incontinence, bloody or mucoid discharge, and a foul odor. In some cases, the patient is able to reduce the prolapse manually, whereas in others the tissue becomes edematous, and a red ulcerated mass protrudes from the anus (Fig. 86.8). Reduction may be attempted by placing the patient prone and applying an osmotically active solution, such as sucrrose-soaked gauze, to the mass. After several minutes, gentle pressure may be applied to guide the tissue back into the rectal vault. Care should be taken not to poke at the tissue, because this could cause penetration from trauma. When this is successful, the patient may be discharged with agents to relieve constipation. Surgical repair often is necessary. 19

In children up to 4 years of age, procidentia often is associated with chronic constipation or diarrheal disease. However, it may herald the presence of malnutrition, parasitic infection, or cystic fibrosis. Children usually have mucosal prolapse. The parent reports protrusion during defecation, with small amounts of mucus or blood. This condition must be distinguished from a protruding juvenile polyp and intussusception. Gentle reduction may be attempted. Increasing the dietary fiber and fluid intake frequently is successful as first-line therapy.

Rectal Foreign Bodies

Principles

Anorectal foreign bodies may result from the use of the anus for sexual gratification, although they also are found in children, psychiatric patients, and victims of assault or iatrogenic injury. Most objects are introduced directly into the anus, but some become lodged there after oral ingestion. Foreign bodies must be removed to prevent mucosal lacerations, intestinal perforation and obstruction, sepsis, and peritonitis. 1

Some foreign bodies that are ingested orally pass through the GI tract and subsequently become lodged in the rectum or anal crypts. Patients at highest risk for ingested foreign bodies are children, psychiatric patients, and body packers.

Clinical Features

Rarely, a foreign body such as an enema tip or broken rectal thermometer is introduced iatrogenically. In most cases, the foreign body is placed deliberately by the patient or a partner for medicinal or sexual purposes. Objects that are commonly retrieved include fruits and vegetables, household items, especially those whose dimensions resemble the penis, and items purchased specifically with an anal erotic intent. By the time patients arrive at the ED, sometimes days after the introduction of the foreign body, they have likely tried to remove it at home. The history of the injury often is reluctantly given or is vague and inconsistent. The initial ED evaluation, conducted in a nonjudgmental manner, should ascertain the type of foreign body involved, how long it has been there, what attempts have been made to remove it, and whether the patient has fever, abdominal pain, or rectal bleeding. The possibility of assault should be considered.

Physical examination begins with an external examination for signs of trauma. If no sharp objects are suspected, a digital rectal examination and anoscopy may reveal the foreign body, lax sphincter, or mucosal injury. An abdominal examination may demonstrate signs of perforation or obstruction.

Diagnostic Testing

The foreign body may be visible on abdominal radiographs, or its presence may be inferred by a nonspecific gas pattern, free air, or signs of intestinal obstruction. If perforation is suspected, water-soluble contrast material can be introduced to delineate radiopaque foreign bodies.

Management

Treatment depends on the location and type of object found. In general, objects that are soft and low-lying (<10 cm from the anal
Other creative ways to remove foreign bodies in the ED have been successful, and an individualized strategy for each patient is essential. Large, hard, fragile objects and those that have migrated proximally are difficult to remove without anal dilation and instrumentation to assist in the passage through the sacral curve and sphincters. These are best performed with the patient under general anesthesia. After the removal of the foreign body, one should consider the possibility of mucosal tears or perforations. Discharge instructions should warn the patient about signs and symptoms of perforation, peritonitis, and sepsis.

Several methods are effective for removal. The easiest is to grasp an edge of the foreign body with forceps and apply traction while the patient bears down. Most foreign bodies in the rectum do not have a convenient place to grasp, so other methods are needed. A Foley catheter can be placed beside the foreign body and the balloon inflated proximally to it (Fig. 86.10). This breaks the suction of the rectal wall mucosa and provides a way to guide the object out of the rectal vault. Hollow objects may be filled with plaster of Paris, with an inset inflated Foley catheter to be used as a handle.

Other creative ways to remove foreign bodies in the ED have been successful, and an individualized strategy for each patient is essential. Large, hard, fragile objects and those that have migrated proximally are difficult to remove without anal dilation and instrumentation to assist in the passage through the sacral curve and sphincters. These are best performed with the patient under general anesthesia. After the removal of the foreign body, one should consider the possibility of mucosal tears or perforations. Discharge instructions should warn the patient about signs and symptoms of perforation, peritonitis, and sepsis.

**KEY CONCEPTS**

- Anorectal conditions can be differentiated according to an algorithm (see Fig. 86.2), which addresses the presence or absence of pain, bleeding, swelling, and pruritus, in combination with an assessment of the patient’s overall health.
- Patients who seek treatment for nonspecific anorectal complaints should be evaluated for the presence of underlying systemic disease (e.g., cancer, diabetes mellitus, immunodeficiency) because disorders of the anus may herald the initial presentation of associated conditions.
- Patients with any STD should be evaluated for HIV infection and questioned about the use of the anus for sexual purposes and the possibility of domestic violence or abuse.
- Most anorectal conditions can be symptomatically improved by adherence to the WASH regimen (warm water, analgesics, stool softeners, high-fiber diet).
- Thrombosed external hemorrhoids are covered by modified anoderm and may be excised and drained within 48 hours.
- Internal hemorrhoids are covered with mucosa and should be referred to colorectal surgeon for definitive management.
- Acutely thrombosed, gangrenous fourth-degree internal hemorrhoids should be referred urgently to a surgeon.
- Superficial abscesses may be drained in the ED.
- Fistulous tracts should not be probed.
- Pilonidal abscesses should be drained with needle aspiration or a longitudinal incision off the midline.
- Pruritis ani is caused by a variety of conditions, including infection, topical irritants, cutaneous conditions, cancer, and hypersensitivity to foods and drugs (see Box 86.5).
- Sensitivity is required when managing patients with anorectal foreign bodies. Health care provider safety is imperative when evaluating foreign bodies with sharp edges.
- Distal foreign bodies often can be removed in the ED using creative means, whereas proximal or sharp ones should be removed under general anesthesia in the operating room.

CHAPTER 86: QUESTIONS & ANSWERS

86.1. Which of the following statements regarding hemorrhoids is true?
A. Most hemorrhoidal bleeding is venous.
B. Painful bleeding is the most common symptom.
C. Portal hypertension does not cause hemorrhoids in adults.
D. Seventy-five percent of pregnant women experience late-pregnancy hemorrhoids.
E. Traumatic deliveries do not predispose to postpartum hemorrhoids.

Answer: C. Portal hypertension does not predispose to hemorrhoids, except in children. Bleeding in these cases is likely from rectal varices. Most hemorrhoidal bleeding is from the superior rectal artery and thus IS bright red. Approximately one-third of pregnant patients experience hemorrhoids in the third trimester or postpartum period. Traumatic deliveries can result in hemorrhoid development. Painless bleeding with defecation is the most common symptom (pain usually occurs if hemorrhoids are thrombosed).

86.2. What is the most common cause of sudden-onset rectal pain?
A. Anal fissure
B. Proctalgia fugax
C. Sacral radiculopathy
D. Thrombosed external hemorrhoid
E. Thrombosed internal hemorrhoid

Answer: A. Anal fissures typically result from superficial tears in the anoderm, usually occurring in the posterior midline. The pain is heightened by secondary spasm of the anal sphincter.

86.3. When performing an incision and drainage of a pilonidal cyst, which of the following is the most appropriate method?
A. Elliptic incision
B. Horizontal incision at the center of the affected area
C. Horizontal incision at the lower portion of the affected area
D. Longitudinal incision along the midline
E. Longitudinal incision lateral to the midline

Answer: D. Third-degree internal hemorrhoids may be manually reduced in the emergency department (ED) but are unlikely to heal spontaneously. Referral for operative therapy is curative. Excision of internal hemorrhoids is contraindicated. Acutely thrombosed external hemorrhoids may be excised in the ED. Temporizing measures include using the WASH regimen—using warm water to encourage reduction of the protruded hemorrhoids, maintaining hygiene, analgesics, stool softeners to ease passage of stool, and a high-fiber diet. Topical corticosteroids may be used for 1 or 2 days during an acute exacerbation, but their continued use promotes skin breakdown and itching. A sucrose solution may prove helpful in reducing procidentia (rectal prolapse). A thorough history should be obtained and a physical examination performed to learn if an underlying medical condition may be associated with the hemorrhoids.

REFERENCES
The evaluation of renal disease in the emergency department (ED) requires an integrative approach incorporating the urinalysis, serum and urine chemical determinations, and renal imaging studies. Combined, this approach assesses the degree of renal dysfunction and establishes the foundation for distinguishing acute kidney injury (AKI) from chronic kidney disease (CKD).

**ACUTE KIDNEY INJURY**

The hallmark of AKI (formerly termed acute renal failure [ARF]) is progressive azotemia, which commonly is accompanied by a wide range of other disturbances, depending on the severity and duration of renal dysfunction. These include metabolic derangements (eg, metabolic acidosis, hyperkalemia), disturbances of body fluid balance (particularly volume overload), and a variety of effects on almost every organ system (Box 87.1).

The causes of AKI are divided into those that decrease renal blood flow (prerenal), produce a renal parenchymal insult (intradialysis, or obstruct urine flow (obstructive, or postrenal). Identification of a prerenal or postrenal cause of AKI generally makes it possible to initiate specific corrective therapy; if these two broad categories of AKI can be excluded, an intrarenal cause is implicated. The renal parenchymal causes of AKI can be usefully subdivided into those primarily affecting the glomeruli, intrarenal vasculature, or renal interstitium. The term acute tubular necrosis denotes another broad category of intrinsic renal failure that cannot be attributed to a specific glomerular, vascular, or interstitial cause (Fig. 87.1).

Numerous other important systemic and organ-specific effects of renal failure occur. Uremia impairs host defenses, particularly leukocyte function, and infection is a significant cause of morbidity and mortality in AKI. Pericarditis, which has a prevalence of 10% to 20% in dialyzed patients with CKD, also may occur in patients with AKI; urgent dialysis is indicated when associated with a pericardial effusion and tamponade. Neurologic abnormalities in AKI may be precipitated by electrolyte abnormalities, medications, or uremia. Anorexia, nausea, vomiting, gastritis, and pancreatitis also are associated with AKI. Significant gastrointestinal (GI) hemorrhage is seen in about 10% of patients.

Impaired erythropoiesis, shortened red blood cell (RBC) survival, hemolysis, hemodilution, and GI blood loss all play a role in the normocytic normochromic anemia that usually accompanies AKI. Although mild thrombocytopenia may be present, it is the qualitative defect in platelet function, thought to be caused by the effect of circulating uremic toxins, that is more significant and that contributes to these patients’ bleeding tendencies.

**Clinical Features**

When the presence of azotemia or renal failure has been discovered, the first consideration in the ED evaluation should be the possibility of potentially life-threatening complications (eg, hyperkalemia, pulmonary edema). Assuming that these have been satisfactorily ruled out, the next step is to determine whether the condition represents AKI or is the result of preexisting renal disease. The clinical distinction between AKI and CKD often is difficult, especially if old records and laboratory results are not available. The finding of small kidneys on abdominal radiographs or bone changes of secondary hyperparathyroidism on hand films suggests that the renal failure is chronic. Anemia, hypocalcemia, and hyperphosphatemia, on the other hand, should not be relied on to identify patients who have CKD because these abnormalities can develop rapidly in AKI.

In evaluating the patient with azotemia, the emergency clinician uses history, physical examination, and laboratory studies to seek clues to the cause and identify signs and symptoms of uremia, volume overload, or other complications of renal failure. In attempting to identify the cause, the general strategy is to rule out prerenal and postrenal causes before considering the many intrinsic renal causes. First, potential sources of volume loss and causes of decreased cardiac output are sought in the history, and the physician is questioned about lightheadedness, bleeding, GI fluid loss, abnormal polyuria, or symptoms of congestive heart failure (CHF). In men, a history of nocturia, frequency, hesitancy, or decreased urinary stream suggests prostatic obstruction. A history of lower tract symptoms or of abdominal or pelvic tumor in either gender is determined, as is a history of kidney stones or chronic urinary tract infection (UTI). A history of acute anuria, defined as the production of less than 100 mL of urine/day, is most often the result of high-grade urinary tract obstruction, although it also may accompany severe volume depletion, severe acute glomerulonephritis, cortical necrosis, or bilateral renal vascular occlusion. Intermittent anuria, on the other hand, is characteristic of obstructive disease.

Medication use and possible exposure to radiographic contrast agents or other exogenous toxins are other key components of the history. A history of hypertension, dark-colored urine, rash, fever, or arthritis suggests intrinsic renal disease or a multisystem disorder.

The physical examination focuses on signs of volume depletion, such as tachycardia and decreased skin turgor. Documented short-term changes in body weight offer a valuable clue in assessing volume status, particularly in chronically ill patients. In

- AIN
- ATN

**Fig. 87.1.** Evaluation of azotemia. AIN, Acute interstitial nephritis; ATN, acute tubular necrosis.

Prerenal and postrenal causes are considered, the diagnostic and management strategies focus on the intrarenal pathologies.

**Prerenal Azotemia**

Decreased renal perfusion that is sufficient to cause a decrease in the glomerular filtration rate (GFR) results in azotemia. Possible causes are grouped into entities causing intravascular volume depletion, volume redistribution, or decreased cardiac output (Box 87.2). Patients who have preexisting renal disease are particularly sensitive to the effects of diminished renal perfusion.

Prerenal azotemia is characterized by increased urine specific gravity, a blood urea nitrogen (BUN) to creatinine ratio generally between 10:1 and 20:1, urine sodium concentration less than 20 mEq/dL, and fractional excretion of sodium (FENa) less than 1%. The condition generally can be corrected readily by expanding extracellular fluid volume, augmenting cardiac output, or discontinuing vasodilating antihypertensive drugs. However, severe prolonged prerenal azotemia can result in acute tubular necrosis (ATN).

Patients who have CHF or cirrhosis form an important subset of those with prerenal azotemia. These patients often are salt-overloaded and water-overloaded, yet their effective intravascular volume is decreased. Administration of diuretics has the potential to decrease intravascular volume further, resulting in decreased glomerular filtration and prerenal azotemia. For some patients with advanced CHF or hepatic disease, a state of chronic, stable, prerenal azotemia may be the best achievable compromise between symptomatic volume overload and severe renal hypoperfusion.

Glomerular perfusion also may be decreased in patients with normal intravascular volume and normal renal blood flow who take angiotensin-converting enzyme (ACE) inhibitors or, more commonly, prostaglandin inhibitors. All nonsteroidal anti-inflammatory drugs (NSAIDs), including aspirin, inhibit prostaglandin synthesis. Renal vasodilator prostaglandins are critical in maintaining glomerular perfusion in patients with conditions such as CHF, chronic renal insufficiency, and cirrhosis, in which elevated circulating levels of renin and angiotensin II decrease renal blood flow and the GFR. In this setting, a decrease in the addition, suspected bleeding should be specifically excluded. Similarly, volume overload is determined by the assessment of jugular vein distention and attention to the presence of rales or edema.

A distended bladder is percussible when it contains 150 mL of urine, and the dome is palpable abdominally when it contains 500 mL. Ultrasonography can be used to detect bladder distention or postvoid residual volume if there is a question of urinary retention.

A prostate examination in men and pelvic examination in women are necessary components of the examination. The presence of rash, purpura, pallor, or petechiae is noted, as is arthritis, musculoskeletal tenderness, and findings suggestive of infection or malignancy.

**Differential Diagnosis**

The management of AKI requires a systematic approach to the differential diagnoses that may underlie the presentation. Once
production of vasodilator prostaglandins may result in acute intrarenal hemodynamic changes and a reversible decrease in renal function. This phenomenon also is seen with the selective cyclooxygenase-2 inhibitor class of NSAIDs. Other risk factors include advanced age, diuretic use, renovascular disease, and diabetes. This entity is distinct from other renal complications of NSAIDs, including interstitial nephritis and papillary necrosis.

**Postrenal (Obstructive) Acute Kidney Injury**

Obstruction is an eminently reversible cause of AKI and should be considered in every patient with newly discovered azotemia or worsening renal function. Obstruction may occur at any level of the urinary tract but usually is produced by prostatic hypertrophy or functional bladder neck obstruction (eg, secondary to medication side effects or neurogenic bladder; Box 87.3). Intrarenal obstruction may result from the intratubular precipitation of uric acid crystals (eg, with tumor lysis), oxalic acid (as in ethylene glycol ingestion), phosphates, myeloma proteins, methotrexate, sulfadiazine, acyclovir, or indinavir. Bilateral ureteral obstruction (or obstruction of the ureter of a solitary kidney) may be caused by retroperitoneal fibrosis, tumor, surgical misadventure, stones, or blood clots. A sudden deterioration in renal function in the setting of diabetes mellitus, analgesic nephropathy, or sickle cell disease suggests papillary necrosis.

**Intrinsic Acute Kidney Injury**

Of the specific intrarenal disorders that cause AKI, glomerulonephritis, interstitial nephritis, and abnormalities of the intrarenal vasculature are amenable to specific therapy and are important to consider as possible causes. These entities are responsible for only 5% to 10% of cases of AKI in adult inpatients; most are caused by ATN. In adults in whom AKI develops outside the hospital, the incidence of glomerular, interstitial, and small vessel disease is much greater. In children, these entities account for approximately 50% of the cases of AKI (Box 87.4).

**Acute Glomerulonephritis.** This may represent a primary renal process or may be the manifestation of any of a wide range of other disease entities (see Box 87.4). Patients may have dark urine, hypertension, edema, or CHF (secondary to volume overload) or may be completely asymptomatic, in which case the diagnosis rests on an incidental finding on urinalysis. The hematuria associated with glomerular disease may be microscopic or gross and may be persistent or intermittent. Proteinuria, although often in the range of 500 mg/day to 3 g/day, not uncommonly is in the nephrotic range, arbitrarily defined as 3.5 g/day or more. The presence of hematuria, proteinuria, or red cell casts is highly suggestive of glomerulonephritis. Conversely, the absence of red cell casts, proteinuria, and hematuria essentially excludes glomerulonephritis as the cause of AKI.

The specific diagnosis of acute glomerulonephritis caused by primary renal disease often is ultimately made by renal biopsy. However, when glomerulonephritis is secondary to a systemic disease such as systemic lupus erythematosus, the clinical signs and symptoms and results of laboratory assessment aid considerably in narrowing the scope of the differential diagnosis. As a rule, extensive laboratory testing to identify the cause of acute glomerulonephritis is not indicated in the ED setting and is more appropriately performed as part of an inpatient evaluation.

**Acute Interstitial Nephritis.** Acute interstitial nephritis (AIN) is usually precipitated by drug exposure or by infection. Drug-induced AIN is poorly understood, but the absence of a clear relationship to the dose and recurrence of the syndrome on rechallenge with the offending agent suggests that an immunologic mechanism is responsible. The most commonly incriminated drugs are the penicillins, diuretics, and NSAIDs. AIN has been reported in association with bacterial, fungal, protozoan, and rickettsial infections.

Patients with AIN typically have rash, fever, eosinophilia, and eosinophiluria, but it is common for one or more of these cardinal signs to be absent. Pyuria, gross or microscopic hematuria, and mild proteinuria are observed in some cases. A definite diagnosis sometimes can be made only on renal biopsy. Treatment of AIN is directed at removing the presumed cause; infections should be
Intrinsic Renal Diseases That Cause Acute Kidney Injury

**VASCULAR DISEASES**

**Large-Vessel Diseases**
- Renal artery thrombosis or stenosis
- Renal vein thrombosis
- Atheroembolic disease

**Small- and Medium-Sized Vessel Diseases**
- Scleroderma
- Malignant hypertension
- Hemolytic uremic syndrome
- Thrombotic thrombocytopenic purpura
- HIV-associated microangiopathy

**GLOMERULAR DISEASES**

**Systemic Diseases**
- Systemic lupus erythematosus
- Infective endocarditis
- Systemic vasculitis (eg, periarteritis nodosa, Wegener’s granulomatosis)
- Henoch-Schönlein purpura
- HIV-associated nephropathy
- Essential mixed cryoglobulinemia
- Goodpasture’s syndrome

**PRIMARY RENAL DISEASES**
- Poststreptococcal glomerulonephritis
- Other postinfectious glomerulonephritis
- Rapidly progressive glomerulonephritis

**TUBULOINTERSTITIAL DISEASES AND CONDITIONS**

- Drugs (many)
- Toxins (eg, heavy metals, ethylene glycol)
- Infections
- Multiple myeloma

**ACUTE TUBULAR NECROSIS**

- Ischemia
- Shock
- Sepsis
- Severe prerenal azotemia

**NEPHROTOXINS**

- Antibiotics
- Radiographic contrast agents
- Myoglobinuria
- Hemoglobinuria

**OTHER DISEASES AND CONDITIONS**

- Severe liver disease
- Allergic reactions
- NSAIDs

HIV, Human immunodeficiency virus; NSAIDs, nonsteroidal antiinflammatory drugs.

treated and offending drugs discontinued. Renal function generally returns to baseline over several weeks, although chronic renal failure has been reported to occur.

**Intrarenal Vascular Disease of the Kidney.** This can be classified according to the size of the vessel that is affected. Disorders such as renal arterial thrombosis or embolism, which affect large blood vessels, must be bilateral—or affect a single functioning kidney—to produce AKI. Whether to attribute such cases of AKI to a prerenal or intrarenal vascular cause is a matter of semantics. The most common cause of thrombosis probably is trauma; thrombosis also may occur after angiography or may be secondary to aortic or renal arterial dissection. Renal atheroembolism is thought to occur commonly, at least on a microscopic level, after arteriography but is an uncommon cause of AKI. Similarly, patients with chronic atrial fibrillation or infective endocarditis may experience embolization of the kidney but rarely develop AKI as a result. Renal arterial embolism can cause acute renal infarction, generally manifested by sudden flank, back, chest, or upper abdominal pain. Urinary findings, including hematuria, are variable. The diagnosis usually is made by renal flow scanning or arteriography.

Several diseases that affect the smaller intrarenal vessels can cause AKI (see Box 87.4). Patients whose disease is severe enough to cause AKI also are generally found to have hypertension, microangiopathic hemolytic anemia, and other systemic and organ-specific manifestations. Infection with *Escherichia coli* O157:H7 has emerged as a major cause of hemolytic uremic syndrome, an important cause of AKI in children.

Patients with scleroderma (systemic sclerosis) may have so-called scleroderma renal crisis, characterized by malignant hypertension and rapidly progressive renal failure. Whereas vasculitis associated with glomerular capillary inflammation typically causes gross or microscopic hematuria and the formation of red cell casts, vascular involvement of the medium-sized vessels, such as that produced by scleroderma, often spares the glomerular vessels and tends not to produce an active urine sediment. Extrarenal manifestations (eg, rash, fever, arthritis, pulmonary symptoms) are usually evident.

For malignant hypertension, both as a separate entity and as a part of scleroderma renal crisis, appropriate treatment can produce a gratifying remission of AKI. Patients with malignant hypertension have been reported to recover renal function after aggressive antihypertensive therapy, with temporary maintenance with dialysis if necessary. In patients with scleroderma renal crisis, specific therapy with ACE inhibitors has been shown to result in improvement in renal function in a significant proportion of cases.

**Acute Tubular Necrosis.** ATN refers to a generally reversible deterioration of kidney function associated with a variety of renal insults. Oliguria may or may not be a feature. The diagnosis is made after prerenal and postrenal causes of ARF and disorders of glomeruli, interstitium, and intrarenal vasculature have been excluded. In a few disorders, these discrete categories overlap. For example, AKI associated with multiple myeloma or ethylene glycol toxicity is associated with intrarenal obstruction and interstitial disease, as well as a probable direct toxic effect on the renal tubule itself.

The most common precipitant of ATN is renal ischemia occurring during surgery or after trauma and sepsis. The remainder of cases occur in the setting of medical illness, usually as a result of the administration of a nephrotoxic aminoglycoside antibiotic or radiopaque agent or in association with rhabdomyolysis. Multiple causes can be identified in some cases; in others, a definitive cause is never established.
Increased renal perfusion results in a continuum of renal dysfunction that ranges from transient prerenal azotemia at one extreme to ATN at the other. Early during the period of renal ischemia, renal function can be restored completely by restoring renal blood flow but, at some point, continued hypoperfusion results in renal dysfunction unresponsive to volume repletion, and ATN will supervene. ATN may occur in the absence of frank hypotension; even modest renal ischemia may result in ATN in susceptible persons. Individual susceptibility to ATN may be related to the balance of prostaglandin-mediated vasodilator and vasoconstrictor influences on the renal vasculature.

Postischemic ATN can occur in the setting of volume loss from the GI tract (upper or lower), skin, or kidneys or can result from severe hemorrhage or major burns. Heat stroke commonly is associated with the development of ATN, which is thought to result from a combination of volume loss, hyperpyrexia, and rhabdomyolysis. Another cause of ATN is hyperglycemic hyperosmolar syndrome, which can be associated with loss of as much as 25% of total body water. ATN also is seen in the setting of cardiogenic shock, sepsis, and third spacing of fluids in pancreatitis and peritonitis.

ATN is common in postoperative patients, although not all cases can be attributed to intraoperative hypotension or hemorrhage. Concomitant sepsis, increased age, preexisting renal disease, and other comorbid conditions are associated with a worse outcome.

Nephrotoxins constitute the other major cause of ATN. Among the most prominent of these are the endogenous pigments myoglobin and hemoglobin, associated with rhabdomyolysis (Box 87.5). Hypotension secondary to fluid loss into damaged muscle is thought to worsen the effects of myoglobinuria on the renal tubule, as does acidemia. Hemolysis, resulting in the release of hemoglobin into the circulation and hemoglobinuria, can cause ATN but usually only in the presence of coexisting dehydration, acidosis, or other causes of decreased renal perfusion. ATN may be associated with the hemolysis of as little as 100 mL of blood.

ATN associated with rhabdomyolysis is often oliguric; it is characterized by rapid increases in the serum creatinine, potassium, phosphorus, and uric acid levels. Creatine released from muscle is metabolized to creatinine, which may result in serum creatinine level increases of more than 2 mg/dL/day, in contrast to the increase of 0.5 to 1.0 mg/dL/day typically seen in other forms of AKI. The BUN/creatinine ratio often is less than 10:1. Intracellular potassium released from damaged muscle may raise the serum potassium level by 1 to 2 mEq/L in several hours. Likewise, phosphate released from muscle may cause dramatic increases in the serum phosphate level. Uric acid, produced by the metabolism of purines released from damaged muscle, may accumulate to levels high enough to cause acute uric acid nephropathy.

Urine dipstick testing yields a positive result for heme in, at most, 50% of patients with rhabdomyolysis, because myoglobin is rapidly cleared from the serum and may therefore be undetectable in the urine at the time of presentation. Thus a negative result on urine dipstick testing does not rule out the diagnosis. Serum creatine kinase (CK) is cleared much more slowly, so measurement of serum CK levels is a more sensitive test.

Antibiotics and radiographic contrast agents are other nephrotoxins that commonly are implicated in the development of ATN. Aminoglycosides are the most commonly implicated antibiotics. Higher doses and longer duration of therapy are associated with higher serum drug levels, leading to greater accumulation of drug in the renal parenchyma and a greater likelihood of nephrotoxicity. Increased age, impaired renal function, dehydration, and exposure to other nephrotoxins are additional risk factors. Once-daily administration of a somewhat higher dose is associated with less nephrotoxicity but has equal effectiveness.

Aminoglycoside-induced ATN typically has a gradual onset. Clinically significant renal dysfunction usually occurs only after several days and often after more than 1 week of therapy. However, renal failure can develop as late as 10 days after a drug has been discontinued, an observation that appears to be explained by the prolonged tissue half-life characteristic of these agents. Renal function returns to normal after an average of 6 weeks, but the condition occasionally progresses to permanent renal injury.

Radiographic contrast agents constitute a common cause of hospital-acquired renal insufficiency. AKI produced by these agents has been defined as an increase in serum creatinine level of 25% over baseline, with a temporal relation to contrast medium administration and in the absence of other identifiable causes. Radiocontrast agent–induced ATN encompasses a spectrum ranging from asymptomatic nonoliguric renal insufficiency to severe renal failure requiring dialysis, but most cases are mild. It may occur after any procedure involving intravascular administration of contrast material. Typically, an increase in the serum creatinine level is noted within 3 days of exposure, with a return to normal within 10 to 14 days.

The most important risk factors for radiocontrast agent–induced ATN are preexisting renal insufficiency, diabetes mellitus, multiple myeloma, age older than 60 years, volume depletion, and higher doses of contrast material. Among these, preexisting renal insufficiency is the most important. Diabetic patients with a serum creatinine level less than 1.5 mg/dL are at low risk for the development of radiocontrast agent–induced ATN, whereas those whose serum creatinine level is greater than 1.5 mg/dL are at significant risk. Volume depletion appears to be an independent risk factor, and aggressive volume expansion before contrast exposure has been shown to have a protective effect. Finally, large doses and repeated doses of contrast material are associated with increased risk of ATN, particularly if a second study is performed within 72 hours of the first.

In combination with periprocedural hydration, N-acetylcysteine decreases the incidence of contrast-associated ATN, although this has not been a consistent finding in published studies. Modest volumes of intravenous normal saline (3 mL/kg over 1 hour, followed by 1.5 mL/kg/hr for 4 hours after contrast exposure) appear to be effective in decreasing the likelihood of nephrotoxicity; sodium bicarbonate does not appear to offer an advantage over normal saline.

**Box 87.5**

Causes of Pigment-Induced Acute Kidney Injury

- Rhabdomyolysis and myoglobinuria
  - Crush injury
  - Compartment syndrome
  - Electrical injury
  - Myonecrosis from coma or immobilization
  - Acute arterial occlusion
  - Vigorous exertion
  - Status epilepticus
  - Hyperthermia/heat stress
  - Metabolic myopathy
  - Drugs/toxins
  - Hypokalemia
  - Hypophosphatemia
- Hemoglobinuria
  - Acute hemolysis
  - Transfusion reaction
  - Drugs/toxins
  - Infections

G6PD; Glucose-6-phosphate dehydrogenase; RBCs, red blood cells.
Diagnostic Testing

The laboratory evaluation begins with a dipstick and microscopic urinalysis and measurement of urine output. BUN, serum creatinine, urine sodium, and FENa levels are determined to help evaluate renal function and provide clues about the cause of AKI. A complete blood count, serum electrolyte panel (expanded to include calcium, phosphorus, and magnesium determinations), electrocardiogram (ECG), and chest radiograph help establish the patient’s baseline status and provide information about possible complications.

Urine Volume

Urine flow does not diminish until the GFR is sharply decreased; thus, urine volume is a poor indicator of renal dysfunction. Oliguria, defined as a urine volume of 100 to 400 mL/24 hr, may be seen with prerenal (blood flow–dependent), intrinsic (intrarenal), or postrenal (obstructive) causes of AKI. Although uncommon, alternating oliguria and anuria (the latter defined as less than 100 mL/24 hr), is a classic indicator of intermittent obstruction, which occurs as urine collects behind an obstructing stone or tumor and then is allowed to flow past as the obstructing material shifts position.

Urinalysis

The standard urinalysis consists of dipstick screening for heme pigment, protein, glucose, ketones, pH, leukocyte esterase, and nitrite and microscopic examination of a spun specimen of freshly voided urine. Dipstick testing for heme and protein can provide important information related to renal function.

Heme. The dipstick detects free hemoglobin from lysed RBCs (or myoglobin) and the hemoglobin inside RBCs, but is more sensitive to free hemoglobin. Although as few as three RBCs/high power field (hpf) can be detected, on any given sample the dipstick may fail to identify 10% to 15% of patients who are otherwise found to have microscopic hematuria, as defined by more than five RBCs/hpf. A positive result on dipstick testing should prompt microscopic examination of the urine. If red cells are seen, the diagnosis of hematuria is confirmed. If the dipstick result is positive but findings on microscopic examination are negative, pigmenturia (myoglobin or free hemoglobin) is suspected.

Protein. The dipstick test for protein, which uses the color change of tetrabromophenol blue, can detect protein at concentrations of 10 to 15 mg/dL but does not yield reliably positive results until the concentration is greater than 30 mg/dL. Moreover, the relation between color intensity and protein concentration is only approximate. The dipstick reagent is three to five times more sensitive to albumin than to globulins and immunoglobulin light chains (eg, Bence Jones protein), an important limitation. False-positive results are caused by alkaline urine, hematuria, or prolonged immersion of the dipstick in the urine. False-negative results are seen with dilute urine.

After dipstick testing has been completed, the sediment from a spun urine specimen is examined under the microscope. A level of two to three RBCs/hpf is commonly accepted as normal.

Casts are formed from urinary Tamm-Horsfall protein—a product of the tubular epithelial cells that gels at low pH and high concentration and when mixed with albumin—or from red cells, tubular cells, or cellular debris in the urine. The composition of a cast reflects the contents of the tubule. Casts are classified according to their appearance or constituents (eg, hyaline, red cell, white cell, granular, or fatty casts). Hyaline casts, those that are devoid of contents, are seen with dehydration, after exercise, or in association with glomerular proteinuria. Red cell casts indicate glomerular hematuria, as seen in glomerulonephritis; the presence of even a few red cell casts is significant. White cell casts imply the presence of renal parenchymal inflammation. Granular casts are composed of cellular remnants and debris. Fatty casts, like oval fat bodies, generally are associated with heavy proteinuria and nephrotic syndrome.

Microscopic examination of the urinary sediment can be helpful in establishing the cause of AKI. A sediment without formed elements or with only hyaline casts is characteristic of prerenal azotemia or obstruction. Red cell casts suggest glomerulonephritis or vasculitis. Fatty casts also suggest glomerular disease. In ATN, the urinary sediment commonly shows granular casts and renal tubular epithelial cells. Large numbers of polymorphonuclear leukocytes are observed in interstitial nephritis, papillary necrosis, and pyelonephritis. Eosinophil-containing casts, appreciated only after staining of the sediment, are typical of allergic interstitial nephritis. Uric acid crystals suggest uric acid nephropathy but are extremely nonspecific; oxalic acid or hippuric acid crystals may be seen in cases of ethylene glycol ingestion.

Serum and Urine Chemical Analysis

Creatinine and Blood Urea Nitrogen. The normal range for the serum creatinine level extends from 0.5 mg/dL in thin people to 1.5 mg/dL in muscular persons. Spurious elevations (up to 2 mg/dL) can be caused by acetoacetate, which cross-reacts with creatinine in some commonly used assays, and by certain medications that cross-react in the assay or reversibly inhibit tubular creatinine secretion, despite a normal GFR, generally causing a creatinine elevation of less than 0.5 mg/dL. Serum creatinine concentration is a function of the amount of creatinine entering the blood from muscle, its volume of distribution, and its rate of excretion. Because the first two are usually constant, changes in the serum creatinine concentration generally reflect changes in GFR. The creatinine clearance is commonly estimated by the Cockcroft-Gault equation:

\[
\text{Creatinine clearance (mL/min)} = \left(\frac{[140 - \text{age}] \times \text{weight}}{72 \times \text{serum creatinine}}\right) \times 0.85 \text{ (if female)}
\]

Under steady-state conditions, if the GFR is halved, the serum creatinine doubles. Abrupt cessation of glomerular filtration causes the serum creatinine level to rise by 1 to 2 mg/dL per day. Thus, a daily increment of less than 1 mg/dL suggests that at least some renal function has been preserved. Rhabdomyolysis releases creatine into the plasma and may cause the serum creatinine level to increase by more than 2 mg/dL per day. The BUN level also rises with renal dysfunction but is also influenced by many extrarenal factors. Increased protein intake, GI bleeding, and the catabolic effects of fever, trauma, infection, and drugs such as tetracycline and corticosteroids all increase protein turnover and result in increased hepatic urea production and increased BUN levels. Conversely, the BUN level tends to be decreased in patients with liver failure or protein malnutrition.

When glomerular filtrate has been formed, renal urea clearance is largely a function of flow rate. Urea clearance is thus decreased in patients with prerenal azotemia or acute obstruction, despite preservation of tubular function. In such cases, the BUN/creatinine ratio usually is greater than the normal value of 10:1, whereas this ratio usually is not markedly increased in cases of uncomplicated intrinsic AKI.

Urine Sodium and Fractional Excretion of Sodium. Normally, urine sodium concentration parallels sodium intake. A low urine sodium concentration thus indicates not only intact tubular
reabsorptive function but also the presence of a stimulus to conserve sodium. The urine sodium concentration, as well as the FENa, an additional measure of tubular sodium handling, helps distinguish between the two most common causes of AKI, prerenal azotemia and ATN.

Urinary indices are most helpful in oliguric patients. An oliguric patient with a urine sodium concentration less than 20 mEq/L and FENa less than 1% is likely to have prerenal azotemia, whereas a urine sodium concentration more than 40 mEq/L and FENa more than 1% suggest ATN. Values in patients with prerenal azotemia overlap somewhat with those in patients with nonoliguric ATN, particularly if the renal injury is mild and some capability to retain sodium has been preserved. Thus, intermediate values for urine sodium concentration and FENa are of little help in differentiating between the two conditions. The administration of mannitol or a loop diuretic within the several hours preceding urine collection also may make interpretation of urine values difficult because the urinary sodium level will tend to be higher and the urine less concentrated, causing the results in prerenal azotemia to resemble those in intrinsic renal failure.

In glomerulonephritis, the urinary indices generally reflect intact tubular sodium handling, but the diagnosis is more accurately made by urine microscopy. In obstructive uropathy, the values of the urinary indices depend on the duration of obstruction and cannot be relied on to indicate the presence or absence of obstruction.

Renal Imaging

Renal imaging is often helpful in the evaluation of the patient with kidney dysfunction, particularly when obstruction is suspected. Contrast-enhanced computed tomography (CT) scanning provides an anatomic image of the urinary tract but does not provide an evaluation of renal function. The classic CT findings of obstruction are kidneys that are normal to large in size, nephrograms that become increasingly dense, and delayed opacification of dilated collecting systems. However, contrast-enhanced CT subjects the kidneys of an already azotemic patient to the risk of an additional potential insult from the contrast agent. Thus, techniques such as ultrasonography and CT that do not involve contrast administration are much preferred for patients with preexisting renal insufficiency (Fig. 87.2).

Computed Tomography. Noncontrast CT may be useful in evaluating some azotemic patients. Hydronephrosis can be recognized without the use of contrast material. Often, dilated ureters can also be seen without contrast enhancement, and the level of obstruction can be determined. The cause of obstruction (eg, bilateral stones, lymphoma, retroperitoneal hemorrhage, metastatic cancer, retroperitoneal fibrosis) often can also be delineated. Occasionally, bilateral ureteral obstruction produced by malignancy or retroperitoneal fibrosis may not cause detectable proximal dilation of the urinary tract. When noninvasive studies yield negative results, the diagnosis of obstruction can be made by retrograde pyelography or antegrade pyelography performed via a percutaneous nephrostomy.

Ultrasonography. Ultrasonography is a safe and reasonably reliable method for excluding obstruction as a cause of AKI. The normal kidney shows an echo-free renal parenchyma surrounding the echogenic central urothelium of the renal pelvis and calices. The sonographic appearance of the kidney in obstruction is that of an enlarged, central, sonoluent area that spreads the normal central echo densities. A similar pattern may be produced by renal cysts, but without associated ureteral dilation. Dilation of the collecting system generally is apparent within 24 to 36 hours after the onset of obstruction, but obstruction may not be evident in patients who are evaluated early in the development of obstructive AKI.

Analysis of Information

Prerenal azotemia is suspected in the setting of volume loss, volume redistribution, or decreased effective renal perfusion. It typically is associated with a normal urinalysis, high BUN/creatinine ratio, increased urine osmolality, urine sodium concentration less than 20 mEq/L, and FENa less than 1%. A rapid response to volume repletion also is characteristic.

Urethral or bladder neck obstruction is documented by the finding of significant amounts of residual urine in the bladder by catherization or ultrasound examination after the patient has voided or attempted to void spontaneously. An important point is that the ability to void does not rule out obstruction. In fact, the urine volume in the presence of obstruction may range from zero to several liters per day. Flank pain is likewise an insensitive marker for obstruction. Urine indices and the BUN/creatinine ratio tend not to be helpful, although an increase in the latter is common in obstruction. A renal parenchymal disorder often can be diagnosed by its manifestations on microscopic urinalysis or by associated extrarenal manifestations (eg, with multisystem disease) or clinical setting (eg, recent exposure to a new medication). The absence of evidence of prerenal or postrenal causes in a patient with AKI may be taken as presumptive evidence of an intrarenal parenchymal process. Among these, the possibility of an acute or ongoing vascular insult should be kept in mind because timely intervention may be important in preserving ultimate renal function.

Management

ED management of AKI is directed at reversing decreases in GFR and urine output (if possible) while minimizing further hemodynamic and toxic insults, maintaining normal fluid and electrolyte balance, and managing other complications of AKI, as required. Because renal failure alters the metabolism and action of many drugs, often in ways that are not predictable, great care should be exercised in prescribing all medications. A compendium of guidelines for drug dosage in renal failure, such as the one by Aronoff and colleagues,7 is of great help for this purpose.

After ensuring that the vital signs are adequate and the patient is in no immediate danger from volume or metabolic derangements, the next step is to correct prerenal and postrenal factors,
intravascular volume is repleted in hypovolemic patients and maintained in euvo-
lemic patients by matching input to measured and insensible output. Inadequate cardiac 
output is augmented when possible. Postrenal or obstructive AKI is treated by restoration of normal urine outflow. Bladder outlet obstruction may be relieved by passage of a Foley catheter, whereas upper tract obstruction may require percutaneous nephrostomy.

Renal insufficiency secondary to NSAIDs generally is reversible after withdrawal of the causative agent. For patients who are at increased risk but require treatment with NSAIDs, a short-acting preparation (eg, ibuprofen) should be prescribed, and follow-up monitoring of renal function and the serum potassium level should begin within days rather than weeks. If renal function is unchanged after a short course of treatment, adverse effects from continuing therapy are unlikely, although other potential mechanisms for the development of renal dysfunction (eg, interstitial nephritis) should be kept in mind.

Treatment of postrenal AKI consists of relief of the obstruction. In the absence of infection, full renal recovery is possible, even after 1 to 2 weeks of total obstruction, although the serum creatinine level may not return to baseline for several weeks. Because the onset of irreversible loss of renal function with obstruction appears to be gradual, a few days’ delay in diagnosis generally is considered acceptable. Still, common sense dictates that obstructions should be detected and relieved promptly.

When prerenal and postrenal factors have been ruled out, the challenge is to identify the cause of intrinsic renal AKI, keeping in mind the multitude of known possible causes (see Box 87.4). The differential diagnosis can often be significantly narrowed by considering the clinical setting and physical and laboratory findings. The clinical picture is often most consistent with the broad category of ATN.

Patients who have oliguric AKI have a significantly higher mortality rate and much greater risk of complications than those who are not oliguric. The difference in prognosis may simply reflect a more severe renal insult in patients who are oliguric, however, and it is not clear that interventions aimed at converting oliguric to nonoliguric AKI have a beneficial effect on renal function or mortality. Nevertheless, because nonoliguric patients are easier to manage, an attempt to increase urine flow is warranted.

The use of loop diuretics or mannitol often is effective in increasing urine flow when intravascular volume deficits have been corrected. Furosemide has not been shown to shorten the clinical course or affect mortality. Mannitol appears to be most useful when given at the time of or shortly after the renal insult; the recommended dose is 12.5 to 25 g, intravenous (IV). If urine output does not increase, further doses may cause hyperosmolality and clinically significant intravascular volume overload in patients with impaired renal function. Dopamine also has been used, with and without furosemide, in an effort to increase urine output, but has not been proven effective.

Certain specific considerations apply to toxin-induced ATN. Pigment-induced ATN may be prevented by avoidance of hemo-
lysis and muscle injury and correction of the factors (eg, dehydration, acidemia) known to predispose patients with pigmentation to the development of renal failure. When hemolysis or rhabdo-
molysis has occurred, treatment is directed at eliminating the cause and preventing the development of renal failure.

Mannitol has been shown to prevent AKI in experimental models of myoglobinuria, presumably by inducing osmotic diure-
sis and decreasing intratubular deposition of pigment. Furose-
mide, on the other hand, has not consistently shown a beneficial effect. Other studies have suggested that myoglobin precipitates in an acidic urine but not in an alkaline urine. Thus, aggressive volume repletion, alkalinization, and mannitol infusion have traditionally been recommended after crush injuries to reduce the likelihood or severity of AKI, although there is some evidence that aggressive volume resuscitation alone may be equally effective. When AKI has occurred, management is similar to that for other forms of AKI, but early dialysis may be required to control rapidly developing hyperkalemia, hyperphosphatemia, and hyperuricemia.

Patients who have radiocontrast agent–induced ATN usually require only supportive therapy. A more significant aspect of ED management is preventing the occurrence of contrast nephropathy, particularly by identifying risk factors in patients for whom contrast studies are being considered. BUN and serum creatinine levels should be checked before contrast exposure in a patient with risk factors, the patient should be volume-repleted before the study, and the administered dose of contrast agent should be kept as low as possible. Multiple studies should be avoided, as should concomitant use of other nephrotoxins. N-acetylcysteine given before and after contrast administration appears to decrease the incidence of contrast nephropathy.

In addition to general measures aimed at minimizing decreases in GFR and increasing urine output, an important component of the management of AKI is the prevention or control of systemic complications. Of particular significance in this regard are metabolic derangements (eg, hyperkalemia, hypocalcemia, hyperphos-
phatemia, metabolic acidosis) and complications of volume overload (eg, hypertension, CHF).

Hyperkalemia and Other Metabolic Derangements

Hyperkalemia. The most common metabolic cause of death in patients with AKI results from an inability to excrete endoge-

nous and exogenous potassium loads. In oliguric patients, the serum potassium level typically increases by 0.3 to 0.5 mEq/L per day, but greater increases occur in catabolic, septic, or traumatized patients and in the presence of acidosis or exogenous potassium loads from diet or medication. This is of particular concern in patients with rhabdomyolysis and associated AKI.

Hyperkalemia results in serious disturbances in cardiac electrophysiology that may culminate in cardiac arrest. Although some hyperkalemic patients note muscular weakness, most are asymptomatic until major manifestations of cardiotoxicity appear. Accordingly, detection of hyperkalemia is a primary consideration in these patients. Electrocardiographic changes correlate only roughly with the serum potassium level. Mild hyperkalemia (serum potassium < 6.0 mEq/L) may be cautiously observed without specific treatment while all exogenous sources of potas-

sium are eliminated. If the serum potassium level is greater than 6.5 mEq/L, and particularly if electrocardiographic changes are present, urgent intervention is necessary.

When cardiotoxicity must be reversed immediately (eg, when there is hemodynamic compromise), IV calcium (10 mL of 10% calcium gluconate infused over 2 minutes, repeated after 5 minutes if necessary) is the treatment of choice. Calcium directly antagonizes the membrane effects of hyperkalemia. IV insulin, given with glucose to prevent hypoglycemia, temporarily shifts potas-

sium to the intracellular space. Bicarbonate appears to be less effective in shifting potassium into cells than once thought. It should be used with caution in patients with renal failure because of its potential to cause volume overload and provoke hypocalcemic tetany or seizures. The safety and efficacy of β-agonists in hyperkalemic patients have been well documented; like insulin, inhaled albuterol (in a dose of 10–20 mg) causes potassium to move into cells, thereby controlling hyperkalemia for 2 hours or more. Sodium polystyrene sulfonate (Kayexalate), a potassium-binding ion exchange resin, has long been adminis-

tered with sorbitol to promote elimination of potassium from the body, but is no longer considered to be effective or free of adverse effects.
**Hypocalcemia.** This is a common feature of AKI and can develop rapidly after its onset. Vitamin D–dependent intestinal absorption of calcium is decreased in AKI because of decreased renal synthesis of 1,25-dihydroxyvitamin D. Another factor promoting hypocalcemia is the complexing of calcium with retained phosphate. Rhabdomyolysis-associated AKI, in particular, is often associated with the deposition of complexed calcium in muscle and other tissues. Asymptomatic hypocalcemia requires no immediate treatment, but subtle or frank tetany should be treated with IV calcium (10–20 mL of 10% calcium gluconate infused over several minutes).

**Hyperphosphatemia.** Hyperphosphatemia resulting from decreased renal elimination of phosphate is another common feature. The serum phosphorus level usually ranges from 6 to 8 mg/dL but may be much higher with rhabdomyolysis or in catabolic states. A calcium–phosphate product greater than 70 mg²/dL² may result in metastatic soft tissue calcification. Hyperphosphatemia often is treated with oral calcium-based antacids that bind ingested phosphate in the gut.

Acids produced in normal metabolic processes accumulate in AKI and are buffered in part by serum bicarbonate, resulting in a decrease in the serum bicarbonate level and a high anion gap metabolic acidosis. Compensatory hyperventilation may be mistakenly attributed to primary cardiac failure or volume overload. The metabolic acidosis associated with AKI usually is mild, and treatment generally is not necessary if the serum bicarbonate level is greater than 10 mEq/L. Overzealous correction may result in hypokalemia, hypocalcemia, or volume overload.

**Hypermagnesemia.** This may complicate AKI when patients are given magnesium-containing antacids or laxatives. Thus, these products, as well as magnesium itself (eg, when given for preeclampsia or for treatment of arrhythmia or wheezing), should be avoided in the setting of AKI.

**Disturbances of Volume Regulation.** These can be expected to occur in most patients with AKI. Some nonoliguric patients excrete enough salt and water to produce intravascular volume depletion if adequate fluid replacement is not provided. Volume depletion prolongs recovery from AKI. Much more commonly, AKI is complicated by volume overload because sodium and water excretion may be inadequate to match even modest intakes. Volume overload is largely responsible for the hypertension often seen in those with AKI and commonly leads to CHF and pulmonary edema. Iatrogenic volume overload is particularly common and can be prevented only by careful attention to fluid intake and output, with prudent estimates of insensible loss. Volume overload can be treated with diuretics or intravenous nitroglycerin while preparations are being made to initiate dialysis.

**Disposition**

Patients with new-onset AKI should be hospitalized. If nephrology consultation and dialysis facilities are not available, transfer to another institution is advisable once volume and metabolic abnormalities have been controlled and the patient is hemodynamically stable.

Decisions regarding dialysis generally are made by the nephrology consultant and take into account many factors, including laboratory test abnormalities and the presence or absence of signs and symptoms of uremia (eg, nausea, vomiting, change in mental status). Many nephrologists choose to initiate dialysis when the BUN level exceeds 100 mg/dL or the serum creatinine level exceeds 10 mg/dL. Intractable volume overload and life-threatening hyperkalemia are the two most common indications for emergency dialysis.

**CHRONIC KIDNEY DISEASE**

CKD denotes kidney damage or decreased renal function for 3 months or longer and is characterized by irreversible nephron loss and scarring. Chronic renal insufficiency, which denotes a condition in which the GFR has been moderately reduced but not to a degree sufficient to cause clear-cut clinical symptoms, has been replaced by an indication of the degree to which the GFR is reduced. End-stage renal disease, now termed kidney failure, describes a condition in which renal function has diminished to a low level and in which serious, life-threatening manifestations can be expected to occur without dialysis or transplantation. At this stage, the kidneys often are shrunken and diffusely scarred to such a degree that it may be impossible to make an etiologic diagnosis, even on pathologic examination.

**Causes**

The causes of CKD are numerous; their relative frequency depends primarily on the population studied. As with AKI, they can be conveniently classified as prerenal (vascular), intrinsic renal (glomerular and tubulointerstitial), or postrenal (obstructive; Box 87.6). Glomerular disease accounts for approximately one-third to half of the cases of CKD; in the United States, diabetic nephropathy forms the largest group of these. Hypertensive nephrosclerosis is another important cause, particularly among blacks, in whom it may be the cause of 25% or more of cases of CKD. Among children and adolescents, reflux nephropathy is the most common cause of CKD. Renal failure related to IV drug use or human immunodeficiency virus disease is a major consideration in some populations. Clues to other specific causes may be gained from elements of the history, physical examination, and laboratory and imaging studies. Although determining the underlying cause of CKD can permit the underlying disease to be treated and can lead to some improvement in renal function in some cases, this is the exception rather than the rule.

Barring renal transplantation, CKD is an essentially irreversible condition generally characterized by a relentless decrease in renal function. The most common problems requiring emergent intervention are severe hyperkalemia and symptomatic volume overload. In the patient with CKD who has an acute problem, the focus should be on the identification and treatment of an intercurrent illness that has caused clinical decomposition, with the goal of returning the patient to a stable, chronically compensated state.

**Pathophysiology**

Progressive loss of renal function eventually results in a recognizable syndrome termed uremia. Clinical manifestations do not generally appear, however, until the GFR has been reduced to approximately 15% to 20% of normal. As the patient becomes unable to excrete an ingested salt or water load promptly, the external balance of sodium and water is affected; volume overload or hypertension or hyponatremia may result. Inability to concentrate the urine is an early manifestation of renal insufficiency and may be manifested as nocturia. Potassium homeostasis is likewise disrupted, and a relatively small potassium load may lead to dangerous hyperkalemia. The acid-base balance is affected because the kidney fails to clear the daily metabolic acid load owing to a decreased ability to excrete ammonium and phosphate; the result is a non–anion gap acidosis in the earlier stages of CKD and a superimposed anion gap acidosis as the GFR decreases further. Calcium and phosphate metabolism is affected as well; retention of phosphate and progressive loss of the kidney’s capacity to synthesize 1,25-dihydroxycholecalciferol, the active form of vitamin D, lead to hypocalcemia, secondary hyperparathyroidism, and eventually the development of renal osteodystrophy.
Nitrogenous byproducts of protein catabolism retained in the blood are the presumed cause of many of the diverse abnormalities of organ function in renal failure. Most patients with CKD show decreased glucose tolerance, although it is rarely severe enough to require treatment unless the medical history includes established diabetes. In the latter case, insulin or other hypoglycemic therapy may need to be continued, but generally at a lower dosage than required before the onset of renal failure because the normal kidney has a major role in insulin degradation. Alterations in lipid metabolism result in elevated low-density lipoprotein levels and hypertriglyceridemia in many patients with CKD.

Clinical Features

Uremia has specific effects on a variety of organ systems. Many of these manifestations are relieved by dialysis, but others are not. A number have been attributed in some degree to the retention of nitrogenous wastes and to derangements in vitamin D and parathyroid hormone metabolism (see earlier).

Cardiovascular System

The cardiovascular system is perhaps most dramatically affected in CKD. Many of the manifestations can be attributed to the effects of chronic volume overload, anemia, hyperlipidemia, alterations in calcium and phosphorus metabolism, and volume- and hormone-mediated hypertension. Pericarditis, with or without pericardial fluid accumulation, also is common in CKD, particularly among patients who have not undergone dialysis.

Pulmonary Effects

Uremic pleuritis, with or without associated pleural fluid collections, may develop in some patients. So-called uremic lung, manifested radiographically by bat wing perihilar infiltrates, represents pulmonary edema and is almost always caused by volume overload or myocardial dysfunction. Noninflammatory pleural effusion caused by volume overload also is fairly common. Of special importance in the ED evaluation is that the radiographic appearance in pulmonary edema may at times be misleading, simulating an infectious lobar infiltrate or even assuming a nodular appearance in some cases.

Neurologic Features

Neurologic dysfunction is common in those with advanced uremia and usually manifests with lethargy, somnolence, difficulty concentrating, or frank alteration in mental status. Seizures may occur, although causes other than uremia alone must be ruled out. Uremic encephalopathy commonly manifests with hiccups, asterixis, or myoclonic twitching. The latter should not be confused with tetany caused by hypocalcemia, which also is common in untreated CKD patients with. In the peripheral nervous system, uremia often causes cramps and a distal sensorimotor neuropathy.

Gastrointestinal System

Anorexia, nausea, and vomiting are nearly constant features of uremia. These GI manifestations are caused by the accumulation of nitrogenous wastes which may be relieved, even in the undialyzed patient, by introduction of a low-protein diet, and seem to correlate roughly with the BUN level.

Dermatologic Features

The skin of patients with CKD has a characteristic yellowish tinge. Uremic frost, the result of the deposition of urea from evaporated sweat on the skin, is a classic finding that like so-called uremic fetor, is seen only rarely now with the widespread use of dialysis (Fig. 87.3). Diffuse pruritus is often a major source of discomfort for the patient with CKD; in some cases, it may be caused by calcium deposition in the skin secondary to derangements in calcium metabolism.

The use of gadolinium-based contrast agents for magnetic resonance imaging has been associated with the development of nephrogenic systemic fibrosis, a potentially fatal disorder that occurs in patients with chronic kidney failure.

Musculoskeletal System

The complex disturbances of calcium and phosphate metabolism in CKD result in renal osteodystrophy, a clinical entity encompassing several overlapping varieties of bone disease that can cause bone pain or frank fractures. Patients with CKD generally are treated with long-term oral calcium and vitamin D in an effort to prevent secondary hyperparathyroidism and uremic
Uremic threatening conditions, including hyperkalemia and myocardial infarction, are in the differential, and a comprehensive evaluation is generally indicated.

In patients without an established diagnosis of CKD, the first consideration in the differential is establishing that the renal failure is chronic rather than acute. An explicit history to that effect, obtained from previous medical records or from the patient or family, provides the most straightforward and reliable confirmation, as does the presence of a dialysis access device on physical examination. If such a history is unavailable, the finding of bilaterally small kidneys, readily detected by plain abdominal radiography or ultrasonography, constitutes equally good evidence. However, the converse is not necessarily true—a finding of normal-sized or large kidneys does not rule out CKD. In such cases, additional diagnostic steps are required to establish the diagnosis. A convincing history of the long-standing presence of the presenting symptoms or of symptoms, such as nocturia, may be helpful in suggesting chronicity, as may a history of familial kidney disease, such as polycystic kidney disease or Alport’s syndrome.

Laboratory abnormalities such as anemia, acidosis, hyperuricemia, hypocalcemia, and hyperphosphatemia can occur in patients with acute kidney failure as early as 10 days after onset. Although urinary findings likewise tend not to be helpful, the presence of broad waxy casts on microscopic examination is suggestive of chronic disease, whereas the finding of an active sediment (eg, red cell casts) is good evidence for an acute process.

Although as a rule chronic kidney failure is irreversible and slowly progressive, an essential component of the ED evaluation is to exclude the possibility of potentially reversible factors (in effect, ruling out “acute on chronic” renal failure) and to ensure that treatable causes of CKD—disorders that if treated might allow for some return of renal function—have not been overlooked. These potentially reversible factors and treatable causes of CKD are important to keep in mind because they represent the only potential opportunity to reverse the patient’s disease rather than simply to manage its results (Box 87.7).

Primary among superimposed reversible factors are those that lead to decreased renal perfusion. Of these, the most common is volume depletion. Regardless of the initiating cause, the process

**Fig. 87.3.** Uremic frost. Note the fine white powder on the skin of this patient with kidney failure.
is exacerbated by the diseased kidney’s impaired ability to conserve sodium and concentrate the urine appropriately. Decreased renal perfusion caused by cardiac dysfunction of any cause is another extremely common and potentially reversible factor. An uncommonly encountered but important vascular cause of reversible deterioration of renal function is scleroderma renal crisis, a syndrome of accelerated hypertension and severe vasoconstriction in patients with underlying scleroderma that can be reversed by timely treatment with ACE inhibitors. Increased catabolism caused by infection, trauma, surgery, corticosteroids, or GI bleeding is another reversible factor that often is responsible for worsening azotemia and the development of uremic symptoms. Drugs and toxins constitute another important group of reversible factors. Not only may these agents exacerbate renal insufficiency by causing intravascular volume depletion (diuretics), decreased renal perfusion (antihypertensive agents), or increased catabolism (tetracycline), they also can cause ATN (radiographic contrast material), AIN (many drugs), or inhibition of renal prostaglandin synthesis (NSAIDs). Particularly noteworthy is the dramatic decrease in renal function produced when an ACE inhibitor is administered to a patient with renal insufficiency caused by bilateral renal artery stenosis or renal artery stenosis in a solitary kidney.

Postrenal reversible factors also are important because of their frequency, particularly obstructive disease in the older male patient and reflux nephropathy in the child. Papillary necrosis should remain a consideration in the diabetic patient, the patient with sickle cell disease, and the patient with a history of long-term analgesic use. Stone disease, retroperitoneal fibrosis, and even rarer entities such as ureteral tuberculosis also should not be overlooked.

Finally, treatment of the underlying disorder that has caused the CKD can occasionally result in the return of some renal function, most notably in cases of myeloma kidney, some forms of secondary glomerulonephritis, and severe hypertensive disease. Although this consideration should relate to long-term care and follow-up, it is appropriate that ED management address this issue to ensure that appropriate evaluation and disposition are arranged.

Diagnostic Testing

See earlier (“Acute Kidney Injury: Diagnostic Testing”).

Management

CKD patients are susceptible to infection, bleeding, and the numerous other complications associated with renal failure, as well as those that may be associated with the underlying causative disorder. Moreover, these patients are more vulnerable to the effects of any intercurrent illness or trauma. Those who are maintained with chronic hemodialysis or peritoneal dialysis are subject to potential complications from the dialysis therapy itself.

Patients with CKD also are uniquely susceptible to iatrogenic illness. First, they are less able to handle fluid and solute loads than normal persons. Just as important, the presence of renal failure significantly alters the metabolism and action of many drugs, often in ways that are not predictable (Box 87.8). Thus the dose and schedule of every agent administered, even those that are apparently innocuous, such as antacids, laxatives, antiemetics, or multivitamin preparations, should be carefully considered, and the hospital pharmacist or other dependable resource consulted. In general, consultation with the patient’s nephrologist is recommended on completion of the initial ED evaluation because management and follow-up monitoring after the patient has left the ED are often complex.

In the United States, most patients with advancing CKD eventually will require dialysis, but several true emergencies may develop in the patient with CKD before chronic dialysis has been instituted. Specific diagnostic and therapeutic considerations apply to the management of these conditions, regardless of whether they occur in dialyzed or undialyzed patients.

Hyperkalemia

Potentially the most rapidly lethal complication of CKD is severe hyperkalemia. As a rule, this condition is clinically silent until it causes potentially life-threatening manifestations. Accordingly, hyperkalemia must be looked for in every patient with CKD. These patients can become severely hyperkalemic when required to handle even modest exogenous and endogenous potassium loads; moreover, even drugs that have only minimal effects on the serum potassium level in normal persons, such as β-blockers and ACE inhibitors, can cause hyperkalemia in these patients. There is concern that the use of succinylcholine in patients with CKD has the potential to cause rapid deterioration in patients who are already hyperkalemic, although this appears to be rare.

An ECG should be obtained whenever hyperkalemia is a possibility and, if signs of hyperkalemia are noted, appropriate therapy should be started immediately, even before laboratory confirmation of a high serum potassium level. Electrocardiographic changes may be completely absent, even when hyperkalemia is severe; thus, a normal ECG does not preclude the need for laboratory confirmation of a normal serum potassium level. A potassium level of 6 mEq/L should be considered potentially dangerous, even though many patients with CKD chronically tolerate levels somewhat above this threshold, without electrocardiographic changes. A patient with CKD who is in cardiac arrest should be assumed to be hyperkalemic and treated accordingly while the usual resuscitative measures are taken. See earlier (“Acute Kidney Injury: Management”) and Table 87.1.

In patients who still retain some renal function, the most effective way to treat hyperkalemia in patients with CKI may be to administer an IV diuretic such as furosemide (if the patient is not hypovolemic) and to provide volume, if necessary. Large doses of diuretic may be necessary for a satisfactory diuresis to be induced. In light of the potential for ototoxicity with the use of loop-active diuretics, these drugs should be administered by slow infusion rather than by bolus and may be contraindicated in patients who also are receiving other potentially ototoxic agents. During the course of any of these therapeutic interventions, the electrocardiographic and serum potassium levels must be monitored frequently.

Pulmonary Edema

Perhaps the most common ED problem in patients with CKD is pulmonary edema secondary to volume overload. Surprisingly,
the diagnosis is not always straightforward. A history of increasing
dyspnea on exertion or paroxysmal nocturnal dyspnea may be
suggestive, but the physical examination may not reveal the
expected signs of CHF, and even chest radiography may be decep-
tive. Recent weight gain or a body weight considerably over dry
weight (typically >5 pounds) is the most reliable clue and, in the
absence of convincing evidence of another cause for dyspnea,
volume overload should be assumed to be the cause.

Treatment of pulmonary edema in the patient with CKD is of
necessity somewhat different from that in other patients. Arrange-
ments for initiation of dialysis should be made as soon as possible
because it is the most rapidly effective means to decrease intravas-
cular volume in the absence of renal function. Other immediate
measures should be instituted in the meantime. Although such
measures may occasionally prove to be effective enough to avoid
dialysis temporarily in patients who possess some residual renal
function, it should nevertheless be anticipated that the response
to even extremely aggressive medical therapy, short of dialysis, will
be inadequate.

The CKD patient with pulmonary edema is placed in the
sitting position, and high-flow oxygen is administered by mask.
The use of continuous or bilevel positive airway pressure (CPAP or
BiPAP) is a useful adjunct for patients with CKD, as for patients
without renal failure. Sublingual nitroglycerin can be adminis-
tered immediately and functions rapidly to reduce preload and
afterload; an IV infusion beginning at 10 to 20 µg/min can be
initiated promptly and titrated to effect. Diuretics are not expected
to be helpful unless the patient has retained a significant level of
renal function.

Infection

Because infection is a major contributor to morbidity and mortal-
ity among patients with CKD, the possibility of serious infection
should be entertained, even when the expected classic findings are
not all present. For example, bacteremia may manifest with fever
alone, just as in other patients with impaired immunity. Patients
with pneumonia may have only vague dyspnea or malaise, symp-
toms that may be attributed to volume overload or uremia. Thus,
all diagnostic possibilities should be pursued, and empirical
broad-spectrum antibiotic coverage often is advisable until infec-
tion has been ruled out in the hospital. Bacteremia resulting from
vascular access infection is common in patients undergoing
hemodialysis, as is peritonitis in patients undergoing peritoneal
dialysis.

A UTI can occur even in patients with minimal urine output
or those with long-standing renal failure. Urinary stasis is
undoubtedly a predisposing factor. However, asymptomatic
pyuria is common in these patients and is not necessarily indica-
tive of infection. For patients with symptoms, urine culture is
helpful in guiding treatment decisions. An upper UTI associated
with a clinical picture typical of pyelonephritis or renal colic
is usually seen in patients with polycystic kidney disease and
requires parenteral treatment. A clinical diagnosis can be made
presumptively in the ED, but invasive measures sometimes are
necessary to document infection and guide therapy. For infected
cysts, lipid-soluble antibiotics (eg, ciprofloxacin, trimethoprim-
sulfamethoxazole) offer the best antibiotic penetration; surgical
intervention for refractory infection sometimes becomes neces-
sary, however.

Dialysis

Dialysis can normalize fluid balance, correct electrolyte and other
solute abnormalities, and remove uremic toxins or drugs from the
circulation when the patient’s kidneys are unable to do so. Dialysis
also can reverse some uremic symptoms, but generally to a lesser
degree, and permit better long-term control of hypertension,
anaemia, and renal osteodystrophy.

Major Dialysis Modalities. The two major dialysis modal-
ities are hemodialysis and peritoneal dialysis. Each is based on a
particular technique whereby the patient’s blood comes into contact with
a semipermeable membrane, on the other side of which is a
specially constituted balanced physiologic solution. Water and
solute diffuse across the membrane by moving along concentra-
tion and osmotic gradients, effectively normalizing the blood’s
composition.
**Hemodialysis.** This requires special access to the patient’s circulation, generally through a surgically created arteriovenous fistula or implanted artificial graft or through a surgically placed tunneled catheter. The vascular access site must be treated with care because hemodialysis cannot be performed without it. Careless manipulation or puncture can cause bleeding, infection, or thrombosis, which may result in loss of the access. The involved arm should not be used for blood pressure determinations, and a tourniquet should not be applied.

In general, blood is drawn and IV lines are established in other locations. In exceptional circumstances, if no other site is available and it is essential to obtain blood samples quickly, the fistula or graft may be used, but with precautions. A tourniquet is not applied, the area is cleansed scrupulously before the puncture, and extreme care is taken not to puncture the back wall of the access. After the puncture, firm but nonocclusive pressure is applied for at least 10 minutes. The presence of a thrill before and after the procedure is documented. Similar precautions are taken in the exceptional cases in which the fistula or graft must be used for IV access. If this is done, an automated infusion pump is essential to control the infusion rate into these relatively high-pressure blood vessels.

**Peritoneal Dialysis.** Here, the patient’s peritoneum functions as the dialysis membrane. Dialysate is infused through a surgically implanted Silastic catheter (Tennckhoff catheter) that penetrates the lower abdominal wall. Fluid exchanges are performed several times daily, typically by the patient at home. As compared with hemodialysis, peritoneal dialysis offers the theoretical advantages of greater patient independence, avoidance of anticoagulation, and smoother control of volume and hypertension, without the intermittent rapid shifts of solute typical of hemodialysis. Medications such as insulin and antibiotics can be administered via the intraperitoneal (IP) route, allowing smoother absorption and more stable blood levels. The main disadvantage of peritoneal dialysis is a significant incidence of bacterial peritonitis, which is, however, usually readily treatable.

**Indications for Dialysis.** The decision to initiate chronic dialysis in the patient with CKD generally is made by the patient’s nephrologist in the setting of a gradually decreasing GFR and progressive manifestations of renal failure. The absolute value of the BUN or serum creatinine level generally is used only as a rough guide to determine when chronic dialysis should be instituted. The provision of vascular or peritoneal access usually has been arranged weeks to months before the anticipated initiation of dialysis to allow the access site to mature and minimize any mechanical complications of the procedure.

For patients who come to the ED with AKI, however, as well as for patients with CKD in whom acute problems have developed, the emergency clinician must be prepared to make the decision to arrange for emergent dialysis (Box 87.9). How urgently dialysis must be initiated depends not only on the severity and acuteness of the presenting problem, but also on the availability of technical facilities and trained dialysis personnel and effectiveness of available temporizing measures for the problem at hand.

The most common problem requiring emergent dialysis, particularly in the patient with CKD, is pulmonary edema secondary to volume overload. In general, the inciting cause is overinjection of fluid and salt in excess of the patient’s greatly diminished renal excretory capacity. Despite the effectiveness of temporizing measures, many of these patients require immediate dialysis—emergency hemodialysis or, in the case of the patient maintained on peritoneal dialysis, intensification of the usual dialysis regimen.

A related problem that may require emergent, or at least urgent, dialysis is malignant hypertension, particularly when associated with hypertensive encephalopathy or cardiovascular decompensation. Because hypertension in patients with renal failure is commonly volume-dependent, correction of volume overload, even if not apparent clinically, is a central component of therapy. Temporizing measures such as the administration of IV nitroglycerin often permit hypertension to be controlled sufficiently for dialysis to be delayed for several hours. In many cases, hypertension and associated symptoms are difficult to control until dialysis permits the volume overload to be corrected. Because blood pressure often is dramatically responsive to reduction of circulating volume, other antihypertensive agents with more prolonged effects should be withheld until after dialysis to avoid hypotension after circulating volume has been acutely reduced.

Severe hyperkalemia is another common indication for emergent or urgent dialysis, particularly in the patient with AKI who is hypercatabolic. In the patient with CKD, hyperkalemia usually is caused by excessive potassium intake, but endogenous causes such as hemolysis or rhabdomyolysis should also be kept in mind. The available temporizing measures can be used to control the serum potassium level, but dialysis remains the most effective means of removing potassium from the body. For rapid control of the serum potassium level, hemodialysis, with its high clearance rates, is preferred to peritoneal dialysis.

Other severe electrolyte and acid–base disturbances, including diabetic ketoacidosis, may sometimes necessitate emergent dialysis. Occasional patients with renal failure and severe hypercalcemia uncontrollable by other modalities (eg, patients with multiple myeloma causing both renal failure and hypercalcemia) may require dialysis. The occasional patient with renal failure in whom severe hypermagnesemia develops after inappropriate therapy or magnesium ingestion may require immediate dialysis to reverse life-threatening paralysis or cardiac dysrythmia. Severe metabolic acidosis in the setting of renal failure is another indication for emergent dialysis, particularly if volume overload or hypocalcemia (with the risk of tetany and convulsions) precludes the administration of bicarbonate.

A related situation is one in which a patient with renal failure has taken an overdose or inadvertently been administered medication that is ordinarily cleared by the kidneys. If the agent is adequately dialyzable and its continued presence in the circulation poses a significant risk to the patient, immediate dialysis can be lifesaving. An example is the ingestion of methanol or ethylene glycol by a dialysis patient. Similarly, ill-advised use of magnesium-containing cathartics or phosphate-containing enemas by patients with CKD can lead to dangerous hypermagnesemia and hyperphosphatemia, respectively, and may necessitate urgent dialysis.

The serum creatinine and BUN levels themselves are not considered definitive indications for dialysis. A creatinine level of 10 mg/dL or BUN level of 100 mg/dL often is used as a guideline for beginning chronic dialysis in the patient with progressive renal failure. In dialyzed patients, however, the serum creatinine level often is considerably greater than 10 mg/dL but is a reflection of total body muscle mass more than of the adequacy of dialysis. The BUN level is a somewhat better indicator; in well-dialyzed persons, it generally is in the range of 50 to 80 mg/dL and is more than

---

**BOX 87.9**

**Indications for Emergency Dialysis**

- Pulmonary edema
- Severe uncontrollable hypertension
- Hyperkalemia
- Other severe electrolyte or acid-base disturbances
- Some overdoses
- Pericarditis (possibly)
100 mg/dL in less well-dialyzed patients. Neither blood level, however, correlates more than roughly with uremic symptoms, even in undialyzed patients, or has any direct bearing on how urgently dialysis should be initiated.

The occurrence of uremic symptoms or signs such as nausea, vomiting, lethargy, or twitching indicates a need for dialysis but does not necessitate immediate initiation of dialysis unless symptoms are severe. Pericarditis, even in the absence of cardiac tamponade, often is considered an indication for urgent dialysis, but pericarditis can also occur in well-dialyzed CKD patients. In a previously undialyzed patient with progressive renal insufficiency, the appearance of pericarditis indicates that it is time to initiate dialysis, although not necessarily on an emergency basis.

**COMPLICATIONS OF DIALYSIS**

A number of complications can be manifest after dialysis is initiated.

**Hemodialysis**

**Vascular Access–Related Complications**

The performance of hemodialysis depends on reliable vascular access, and it is the vascular access device that is responsible for the complications of dialysis that most often require evaluation in the ED setting. These problems must be attended to promptly to minimize the risk of losing the patient’s dialysis lifetime.
